It is true, a physician understands, as no other man can, that vice cannot be stamped out like smallpox by a vigilance committee. He realizes that the sexual appetite is a normal one that demands gratification; but he knows, to the very dregs, the cup of bitterness, the loathsome sickness, the diseased offspring, the premature death and the misery of home life that come from the traffic of prostitution as it has existed for years in New York.

The terrible drain on the community's health that is caused by the protection of vice in this city is enough to demand the presence of a physician on the Committee. The moral question, from the ethical standpoint, is almost trivial compared with the grave physical and economic problems of the question, and we believe that the Committee of Fifteen is facing these wisely and well, but we would be glad to know that it had the benefit of the technical knowledge of a trained medical man.

THE BACTERIA CONCERNED IN THE DEVELOPMENT OF BRONCHITIS.

Up to the present time it must be admitted that our knowledge of the bacteriology of bronchitis has, on the whole, been extremely meagre. Although the subject of considerable investiga-

tion in the past, the etiological significance of the bacteria ordinarily encountered in bronchitic secretion seems less clear than many would suppose, even at the present day. The problem of the infective nature of bronchitis has been so closely linked with that of the bacteriology of the normal air-passages that the conflicting views entertained regarding the latter have necessarily much influenced the interpretation of experimental studies the object of which was the determination of the micro-organisms capable of inducing inflammation of the bronchi under ordinary conditions.

Whilst there can really exist little doubt in the minds of most students of the subject as to the infective character of bronchitis, either that of primary or secondary nature, some investigations, mainly those of Baumgarten, Hoffmann, and Dürck, were, however, sufficient to invite reconsideration of the question whether or not bacteria were normally present in the bronchi and lungs. For the most part those who have studied this question conclude that the healthy bronchi are usually sterile and that the mass of bacteria commonly present in the air are wholly or in large part, at least, arrested in the passage of the inspired air through the upper air-passages, the removal being mainly effected by the nasal mucous membrane and the adenoid tissue of the pharynx. Such is the opinion of Hildebrandt, Müller and Barlow.

W. T. Ritchie (*Jour. of Path. and Bact.*, Dec., 1900), who has recently gone over the ground in connection with his studies upon the bacteriology of bronchitis, takes this view also. The careful research of Béco published two years ago, it is interesting to note, does show that the normal lung may occasionally contain pneumococci, streptococci and sometimes staphylococci, the very organisms which are usually considered as causative factors in bronchitis. This is, however, admittedly exceptional and scarcely of sufficient importance to modify the general conclusions which Ritchie reaches.

The results of Ritchie's studies were based upon careful bacteriological examinations of the bronchial secretions of living and postmortem material. These show that acute bronchitis is always an infective disease induced by no one specific micro-organism; several varieties of bacteria were practically always demonstrated, conclusively showing that in the later stages, at all events, bronchitis is a mixed infection. It is probable that any one of the pathogenic bacteria isolated may singly incite bronchitis; whether this is always so in the beginning is difficult to say, but it is probable that only one organism is often alone the primary excitant.

Among the numerous bacteria considered of causative importance may be mentioned the streptococcus, the diplococcus pneumoniæ, staphylococci, influenza and diphtheria bacilli, bacillus pyocyaneus, colon bacillus and certain encapsulated bacteria; a wealth of saprophytic micro-organisms were likewise isolated. The most important causal bacteria are the pneumococcus and streptococci. The induction of bronchitis by such an excitant as the diphtheria bacillus without throat lesions is of great interest, as is also the finding of the influenza bacillus as a pathogenic factor in bronchitis independent of epidemic influenza; this is in accord with the observations of Wynekoop, Lartigau, and others who have established its presence in various lesions when the epidemic disease was not prevalent. The association of the bacillus pyocyaneus with acute bronchitis adds another lesion to the increasing list in which this organism has conspicuously figured.

Dr. Ritchie's work is the most important contribution to the bacteriology of bronchitis within recent years; and, although by no means conclusive in all particulars, the results will certainly encourage others to investigate along the same general lines, endeavoring to elaborate the subject from a more critical and less general point of view.

THE SURGICAL TREATMENT OF CHARCOT'S JOINTS.

Arthropathia tabica is fortunately of comparatively infrequent occurrence and surgical intervention has not been tried in many cases. In the *Zeitschrift für orthopädische Chirurgie*, Band VII., Heft 2, Ahrens, an assistant of Hoffa in Würzburg, reviews the literature of this subject, and discusses the etiology, pathology, prognosis and treatment of these cases in a thorough manner. He also reports three cases which have come under his care.

He is not inclined to favor operative treatment in these affections as a result of his study of the cases which have been reported in literature. He quotes Ullman's tabulation of eighteen resections of tabetic joints. In ten cases the knee was affected, but in only nine does he believe that the condition was certainly tabes. Out of these nine

cases not a single favorable result is reported. Two of the patients died a short time after operation. In three patients, amputation was necessary later; in one non-union resulted and of the remaining patient no further report is given, which Ahrens considers evidence that the result was not a favorable one. He believes that arthrotomy with drainage is unlikely to give any permanent result and that operative intervention is not indicated except in rare cases in which tuberculosis or a suppurative process supervenes. In the three cases which he reports an orthopedic apparatus giving support to the affected limb was used with decided improvement in all. The patients were able to get about with the apparatus in all of the cases, although previously unable to walk. This leads Ahrens to favor strongly conservative orthopedic treatment in such conditions.

Although the evidence seems to be strong in favor of the conclusions just given, there are still conservative surgeons of good judgment who favor resection and arthrotomy in certain cases of Charcot's joint. Probably too few cases have been reported as yet on which to base any very definite conclusions. At least one or two favorable results have been reported which have escaped Ullman's notice in the tabulation which Ahrens quotes. It is impossible to say just what might be obtained by earlier operation in these cases if an early diagnosis of the condition were possible. In most cases the condition of the patient could hardly be made very much worse even if death resulted.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—The order of the stated meeting of the New York Academy of Medicine for March 7, 1901, is as follows: "Discussion on Alcohol and Alcoholism," by Prof. R. T. Chittenden, of Yale University, and "A Discussion of Alcohol as a Food; Its Direct Action on the Nerve-Cell; Its Effects on Americans, and the Aspect of the Law and the Inebriate," by Drs. A. A. Smith, M. Allen Starr, H. M. Biggs, Walter B. James, J. Ewing, Joseph Collins, and others.

New York State Medical Association.—On February 12th the Orange County Medical Association was organized with Dr. M. C. Conner of Middletown, President; Dr. F. W. Dennis of Unionville, Vice-President, and Dr. C. I. Redfield of Middletown, Secretary and Treasurer. Drs. C. Townsend, R. A. Taylor, W. E. Douglas, E. D. Meyers, Joseph B. Hallett, William Evans, Charles A. Canfield, Edward Woodhull, Henry B. Swartwout and E. A. Nugent were elected members of the various committees required by the By-Laws of the State Association.

The Sullivan County Medical Association was organized on February 19th with the following officers: President, Dr. C. S. Payne, Liberty, N. Y.; First Vice-President, Dr. Frank Howser, Centerville Station, N. Y.; Second Vice-President, Dr. S. W. Wells, Liberty, N. Y.; Secretary, Dr. J. L. C. Whitcomb, Liberty, N. Y.; Treasurer, Dr. C. W. Piper, Wurtsboro, N. Y.

New York Skin and Cancer Hospital.—The Governors of the New York Skin and Cancer Hospital announce the following course of clinical lectures on Syphilis, by members of the visiting and consulting staffs, on Wednesday, at 4.15 p. m.: March 6th—Syphilis as a Disease; Modes of Infection; Extra-genital Syphilis, by L. Duncan Bulkley, M.D. March 13th—Skin Manifestations of Syphilis, by L. Duncan Bulkley, M.D. March 20th—Infantile Syphilis, by A. Jacobi, M.D March 27th—Syphilis of the Mouth, Nose, Throat and Larynx, by D. Bryson Delavan, M.D. April 3d—Syphilis of the Eye and Ear, by David Webster, M.D. April 10th—Syphilis of the Nervous System, by Edward D. Fisher, M.D. April 17th—Syphilis of Internal Organs, by Edward G. Janeway, M.D. April 24th—Syphilis of the Bones and Surgical Relations of Syphilis, by Willy Meyer, M.D. May 1st—Synopsis, Conclusions, and Treatment of Syphilis, by L. Duncan Bulkley, M.D.

The Hospital has just received a second $5,000 from the heirs of Emily A. Watson, of New York, to endow another free bed.

Sanitary Water Patrol.—The Committee on Public Health of the Medical Society of the County of Kings has just completed a report of its investigation of Brooklyn's water supply. After receiving the report, the Society followed out its recommendations by adopting resolutions recognizing that certain sources of the borough's water supply were a menace to health and urging the Department of Health and of Water Supply to establish a sanitary patrol of the whole watershed and to construct a sand filtration plant. The committee reported that Brooklyn's water supply is "primarily a good, clean water of excellent character," obtained from surface ponds and streams and from driven wells. Analysis shows that pollution increases gradually from east to west and reaches its maximum at Springfield and at Baisley's ponds. The Department of Water Supply assured the committee that these two sources have been shut off from use. That drainage from cow and horse stables and vaults pollutes the water supply is shown by analysis, establishing the presence of the bacillus proteus and of the colon bacillus, both of which inhabit the intestinal canal of men and of many domestic animals. The biologist of the department, Dr. Whipple, reported

that, although the water was still polluted, there was an improvement since 1898. The report says the resumption of the patrol system is the only means of assuring a pure water supply for large cities. The report also quotes Water Commissioner Dalton to the effect that with the completion of the Milburn pumping station Brooklyn will be relieved from the danger of a water famine.

New York Eye and Ear Infirmary.—The new "Platt Pavilion," a department of the New York Eye and Ear Infirmary devoted to the reception and care of contagious diseases of the eye, was opened for public inspection last week. The new department has been erected through the generosity of the family of the late Justin A. Bliss. A tablet in the hall of the pavilion reads: "In memory of James N. Platt, by his sister, Evelina C. Bliss, and his nieces, J. Adele Stafford and Ida E. Bliss." The pavilion, which is separated completely from the rest of the infirmary, is a three-story brick structure. It contains at present two public wards, each equipped with six beds. Six single rooms are set aside for the use of patients who pay for accommodations. The building is equipped with the most improved sanitary and mechanical arrangements. It has its own sterilizing and ice-making plants, as well as a small crematory for the destruction of infected material that cannot be sterilized. On the ground floor are a large, well-lighted operating room and rooms for offices and clinics. All the rooms are large and fitted with double sets of blinds, so that any degree of light may be admitted. All the furniture is made of enameled steel or of glass. The beds and chairs are of enameled steel; the table-tops of glass. There is no wooden furniture at all. The building is heated by a new process of pure air passing over coiled heating pipes, and the temperature of each room can be graduated. Provision has been made so that the size of the present building may be increased by an additional two stories. The officials of the infirmary say that it is only a question of a short time when the new addition will be needed. The pavilion as it stands now, so it is said, cost about $40,000. There is only one other hospital for the care and treatment of contagious ophthalmia in America; that in connection with the Massachusetts Eye and Ear Infirmary of Boston.

PHILADELPHIA

Medico-Chirurgical College of Philadelphia.—This institution offers a Special Quiz Course for the Preparation of Candidates for the Medical Corps of the United States Army, Navy and Marine Hospital Services, and for State Board and Hospital Examinations.

Ovariotomy in the Eightieth Year.—Dr. Wilmer Krusen reports the removal of cysts of both ovaries from a woman eighty years of age, the patient making a good recovery. The combined weight of the cyst was fifteen pounds. A notable point was their slow growth, the patient having first noticed the abdominal tumor twenty-six years ago.

Fire at St. Timothy's Hospital.—Fire in the administration building of St. Timothy's Hospital, Roxborough, February 20th, caused a damage estimated at $1,500. No patients are kept in that building and a panic in the wards of the other buildings was averted by the coolness of the nurses. Two night nurses and a watchman who were sleeping in the building escaped without injury.

Dr. Keen to Travel.—Dr. W. W. Keen has asked for one year's leave of absence from his duties at the Jefferson Medical College in order to take a trip abroad which will probably extend around the world. Dr. Keen will start on his journey immediately after the meeting of American Medical Association in June, and will return to resume his teaching and practice in September, 1902.

Editorial Change.—It is announced that Dr. Francis R. Packard will shortly assume editorial charge of the *American Journal of the Medical Sciences*, succeeding Dr. Alfred Stengel, whose rapidly increasing duties have compelled his resignation. Dr. Packard is so widely known to the profession as a writer and clinician as to insure that the *Journal* will, under his management, continue to acceptably fill its high position as the leader among the monthly medical periodicals.

Typhus Fever in Philadelphia.—Frederick Edwards, who came from England on the "Oceanic," February 20th, and wandered about this city for five days, was found to be suffering from typhus fever when admitted to the Philadelphia Hospital Tuesday. He was at once sent to the Municipal Hospital, the house at which he had been staying was fumigated, and every effort is being made to prevent the spread of the disease. The New York health authorities were at once notified.

Hospital Investigation Demanded.—Attorney Tobin of this city has made a protest to the Speaker of the House against the passage of the bill appropriating State money to the West Penn Hospital of Pittsburg and asks for a legislative committee to investigate charges which he prefers against the hospital authorities. Mr. Tobin is attorney for the widow of William H. Daley, a Philadelphian, who died in the West Penn Hospital in February, 1900, under circumstances which gave rise to much comment at that time.

Philadelphia Hospital.—Ten additional physicians and surgeons have been added to the staff of the Philadelphia Hospital as a preliminary to making that institution one of the greatest hospitals in the world. The proposition, as approved by the Mayor and Dr. John V. Shoemaker, President of the Board of Charities and Correction, contemplates the establishment of two new public institutions and the entire rebuilding and reorganization of the Philadelphia Hospital. To insure the highest possible standard of professional

efficiency, the managers of the Medico-Chirurgical College, the medical department of the University of Pennsylvania, and the Jefferson Medical College were invited by the Mayor and Dr. Shoemaker to suggest the names of specialists who would properly represent those institutions upon the staff of the hospital. The staff was enlarged so that each college could name two specialists.

Pennsylvania Medical Journal.—Beginning with the March issue certain changes will be inaugurated in the nature of this publication. In the first place, the publication will hereafter be known as the *Medical Bulletin of the University of Pennsylvania*. Secondly, it will contain no advertising matter. Thirdly, the form will be somewhat changed; the pages will be larger and the matter printed in double instead of single column. These constitute the essential alterations. The policy and scope of the magazine will not, however, be affected thereby; it continues to be the official journal of the Medical Department and Departments allied to Medicine of the University of Pennsylvania Medical Society and of the William Pepper Laboratory of Clinical Medicine. Its contents will consist of original articles, complete and carefully prepared digests of the most recent literature upon a subject of practical or scientific importance, alumni notes and book reviews. The liberality of the Board of Trustees alone has made possible these radical changes in the construction of the magazine. The removal from its columns of all advertising matter converts the publication into one of much greater dignity and one much more befitting the Corporation and School it represents. The attention of the subscribers is further called to the fact that, while the proposed *Bulletin* will contain fewer pages, it will in reality contain more original material than has heretofore been furnished.

CHICAGO.

Medico-Legal Relations of Ocular Diseases and Injuries.—At a joint meeting of the Medico-Legal Society of Chicago and the Chicago Ophthalmological and Otological Society, recently held, this subject was discussed.

Damage Suits from the Standpoint of the Ophthalmologist.—Dr. F. C. Hotz discussed the different valuations people put upon the lost eye. He pointed out the different motives for bringing suits and outlined what physicians and lawyers could do to prevent suits of this kind.

Nervous Affections of Eye Caused by Accident.—Dr. Hugh T. Patrick mentioned the most common complaints, their nature, evolution, detection and prognosis. He also dwelt upon the subjective symptoms and objective signs. He pointed out the difficulty of distinguishing hysteria on account of exaggeration and simulation.

Legal Basis of Compensation in Injuries of Eye.—Hon. Joseph E. Gary, Judge of the Superior Court, discussed this phase of the subject. For injuries inflicted through negligence only, without malice, compensation is the rule at law. Compensation includes not only pecuniary loss, but also physical and mental pain, impaired enjoyment of life, and probable prospects. This rule is uncertain in application, because juries have no guide as to loss, other than pecuniary, except their own judgment. In cases of injury through malice other factors enter into the estimate.

Economic Value of Vision.—Dr. H. V. Wurdemann of Milwaukee, Wis., read a paper on this subject, in which he stated that the earning ability of a bodily function is the only fixed economic factor; visual earning ability can be exactly estimated and is synonymous with full earning ability. He mentioned formulæ for full and visual earning ability. Factors are central visual acuity, visual field, ocular musculature, and ability to compete. Economic and scientific standards for vision were dwelt upon, also the economic limitations of trades. He presented tables and diagrams for mathematical calculation. He stated that pecuniary loss was dependent upon lessened visual powers, the nature of the business, and the age of the individual, and that the economic damage should be made the basis for indemnity. Many examples were given.

Dental Department of the University of Illinois.—The Chicago College of Physicians and Surgeons (Medical Department of the University of Illinois) will soon establish a dental department.

Chicago Lying-In Hospital.—It is reported that the demand for rooms is so great in this institution that the managers contemplate enlarging the building at once. Plans have been prepared and it is expected that the work may be begun in the spring. During the past year 974 patients were treated, and 11,129 visits made.

The Smallpox Situation.—It is said that only 17 new cases of smallpox have occurred during the week. At the close of the previous week there were 44 cases in the isolation hospital; 17 were admitted during the week, and 23 discharged, with no death, 38 remaining under treatment. With one exception the cases are mild. It is announced that the stock of glycerinated vaccine-lymph on hand has ripened sufficiently to make the resumption of vaccination safe.

Clean City Ordinance.—Health Commissioner Reynolds recently stated that ordinary house flies, fleas, mosquitoes and other insects that prey upon man and animals, in addition to rats and mice, are certain carriers of disease. The best way to destroy all of these living pests is to rob them of their food and shelter. Decaying garbage in boxes or on the ground feeds and harbors all of them, hence the speedy collection and prompt destruction of garbage has become within the past year a sanitary necessity that cannot be postponed.

Antitoxin for Diphtheria.—It is estimated that 4,500 lives have been saved in this city during the last five years by the use of the antitoxin treatment in diphtheria cases, according to the

Department of Health. This estimate is reached by comparing the diphtheria death-rate of the five years, 1891-5, before the antitoxin treatment was begun, with that of 1896-1900, computing the number of deaths that might have occurred in proportion to the population in the last period at the percentage rates of the first, and taking the difference between this number and the actual number of deaths. The actual saving of lives thus figured is 4,556, deaths to the number of 8,865 from diphtheria and all croup having been probable, and only 4,309 deaths having occurred. On the money basis of the legislative value of a life, $5,000, this saving represents the sum of $22,780,000, and for the year 1900 alone it represents $5,900,000. These figures may strike the average reader as incredible, but they are an understatement rather than an exaggeration. In the five years the city's antitoxin staff has treated 5,727 cases of diphtheria and croup with antitoxin, of which number only 369 died. The death-rate for the disease in the city in 1891-5 was 11.23 per 10,000 of population, and in 1896-1900 it was 5.45. Against an annual average of 1,482 deaths in the first term, the average in the second is 862.

New Skiagraphic Diagnosis for Renal and Ureteral Surgery.—Dr. G. Kolischer and Dr. L. E. Schmidt presented a paper on this subject before a recent meeting of the Chicago Medical Society. The method consists in passing metal instruments through the ureters to the kidneys and then skiagraphing the same while in position. Numerous skiagraphs were shown to give an insight into the character of the work. In order to find out whether or not injuries to the ureters, pelvis or kidneys could arise, they were obliged to find sounds that were adapted to their purposes. Repeated catheterization of the ureters on cadavers showed complete absence of any traumatism. In order to show the possibilities in this line of investigation the following points were enumerated where this method will oftentimes give the desired information: It will give the exact location of the pelvis of the kidney; the exact course of the ureters; the localization of mechanical obstruction in the ureters; the differential diagnosis of gall-bladder and kidney-stone by the manner in which the sound points; and the scratch marks on the sound will also give information as regards stone.

GENERAL.

Beer Scare and Drinking.—The scare in England about arsenic in beer has done more for the cause of sobriety in a week or two than the combined efforts of all the temperance societies in a number of years.

Land for a Plainfield Hospital.—A plot of land, with 500 feet frontage on Thornton avenue, Plainfield, N. J., valued at $10,000, was offered last week as a gift to the Board of Governors of Muhlenberg Hospital as a site for the new hospital building, by James E. Martin, of Plainfield.

Medical Society of Missouri Valley.—This Society will meet at Omaha, March 21st. The following program is announced: J. W. Cokenower, M.D., of Des Moines, Ia., "New Rectum and Sigmoid in Colostomy;" E. A. King, M.D., of Blockton, Ia., "Chorea;" H. D. Jerowitz, M.D., of Kansas City, Mo., "Scarlet Fever;" A. B. Somers, M.D., of Omaha, "Ante-Partum Diagnosis;" J. Cameron Anderson, M.D., of Omaha, "Vesico-Vaginal Fistula;" C. H. Wallace, M.D., of St. Joseph, "Primary Perineorrhaphy;" J. W. Kime, M.D., of Fort Dodge, Ia., "Treatment of Tuberculosis;" Daniel Morton, M.D., of St. Joseph, subject not announced; A. L. Wright, M.D., of Carroll, Ia., "Mastoid Infection;" O. B. Campbell, M.D., of St. Joseph, "Intestinal Obstruction;" J. M. Aikin, M.D., of Omaha, "Facial Paralysis;" Millard Langfeld, M.D., of Omaha, "Compensation and Failure of Compensation in Heart Disease;" M. F. Weymann, M.D., of St. Joseph, "Chalazial Tumors;" Inez C. Philbrick, M.D., of Lincoln, "Association in Women of Pelvic and Hepatic Disease;" Emma Warner Demaree, M.D., of Roca, "A Case of Sporadic Cretinism;" D. C. Bryant, M.D., of Omaha, "The Pathological Importance of the Accessory Sinuses of the Nose;" J. E. Summers, Jr., M.D., of Omaha, "Clean Surgery versus Mutilating and Unscientific Obstetric Procedures as Practiced Upon the Viable Unborn Infant;" Chas. C. Allison, M.D., of Omaha, "Some Phases of Puerperal Sepsis;" H. Gifford, M.D., of Omaha, "Another Case of Methyl-Alcohol Poisoning;" H. P. Hamilton, M.D., of Omaha, "A Plastic Operation for Pruritis Ani."

Medical Inquiry on Social Evil.—At the New York County Society Dr. Prince Morrow read a paper on the medical aspects of the social evil. Dr. Morrow said that the attempt to regulate vice in European cities by a system of fees and licenses had not been successful. In Paris, he said, the number of licensed houses had decreased from 250 to 40, while the vice itself had spread and increased.

William H. Baldwin, Jr., chairman of the Committee of Fifteen, said that the idea of eradicating the evil altogether was Utopian and that, in his opinion, a little of hell, within certain restrictions, was to be preferred to a great deal of hell. He was speaking only for himself and not for the committee.

Dr. Frederic R. Sturgis advocated the licensing and regulating of the social evil, and cited the experiment of St. Louis.

James B. Reynolds said that the women in this city were already regulated by the police and that the methods for collecting the tax on vice were much better than those of the Paris police.

The members of the Academy voted to investigate the social evil in this city, and authorized their President, Dr. George B. Fowler, to appoint a committee of seven to do it.

Obituary.—Dr. I. N. Jones, one of the best-known Cincinnati physicians, died of pneumonia in that city on Thursday night last. He was the

Cincinnati physician of the Actors' Fund of America. A widow and two sons survive him.

Dr. Pierce B. Fagin, a pioneer of the State of California, died February 21st. Dr. Fagin laid out the site of the city of Des Moines, Ia., in 1846. He was eighty-two years old.

Dr. S. A. Mercer Given, manager of the Burn Brae Sanitarium at Clifton, Delaware County, died February 23d. Dr. Given assumed the management of the sanitarium, which was founded by his father, soon after his graduation from the University of Pennsylvania in 1887.

Dr. Abbott Hodgman died February 26th at his home, 141 East Thirty-eighth Street, of a complication of diseases. He was born at West Townsend, Mass., on November 15, 1832, and studied at Dartmouth and the New York University Medical Colleges. He was once a staff doctor on Blackwell's Island. Dr. Hodgman had charge of the medical department of the city prisons from 1861 to 1868, and he was a member of the commission appointed in 1884 to investigate the condition of tenement houses. He was a trustee of the Metropolitan Museum of Art and of the New York Savings Bank and a member of the New England Society, the American Medical Association, the New York Academy of Medicine and the New York State Medical Association.

CORRESPONDENCE

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, February 16, 1901.

THE PLAGUE AT HULL—PLAGUE-STRICKEN RATS AT BRISTOL—THE MEDICAL HISTORY OF THE LATE QUEEN—HER MEDICAL ADVISERS—THE PLAGUE AT SYDNEY GOOD RESULTS FROM HAFFKINE'S PROPHYLACTIC SERUM.

The outbreak of plague at Hull on a steamer which arrived from Alexandria has increased since my description was written for your last letter, but fortunately the energetic precautions of the sanitary authorities have so far prevented any spread of the disease to the town. On January 14th the third and fourth cases were observed on the vessel and the patients were removed to hospital. Four more of the crew were isolated in the hospital. The vessel was removed from the dock to an appointed mooring station and underwent complete fumigation. The whole of the crew, the nursing staff of the hospital, and others who have been exposed to the infection have submitted to Haffkine's prophylactic treatment. The addresses of all persons associated in any way with the ship were obtained and these individuals were kept under daily observation. The vessel has been thoroughly disinfected. It appears that dead rats were discovered on the vessel when it left Alexandria.

Still another attempted invasion of the United Kingdom by plague has occurred at Bristol. A steamer arrived on January 21st from Smyrna with a cargo of grain. On January 22d it was reported to the Medical Officer of Health that six dead rats had been found in the grain and destroyed by fire. On another being found, it was sent to Dr. Klein for examination. Inoculations showed that the rats had died of plague. When this was discovered most of the cargo had been discharged. Every precaution was then taken. The vessel was kept in the floating harbor and thoroughly disinfected. So far no cases of plague have developed.

The following gossip in relation to what may be called the medical history of the late Queen, though in great part overlooked by the omnivorous press which now eagerly seizes every scrap of information in relation to her Majesty, appears to be quite authentic. Her Majesty's long life cannot altogether be explained by heredity, but was partly the result of careful living. Her mother, the Duchess of Kent, was a firm believer in the medical profession and had her daughter's health very carefully supervised. When the Queen came to the throne the rules laid down for her were carefully followed. Not until some years after her marriage were they relaxed. Later she suffered from indigestion and came under the care of Sir William Jenner, who was for more than thirty years her adviser. His counsels she obeyed with a fidelity remarkable in a woman of such strong and independent mind. Somehow the Queen at first disliked doctors and all the immense mental power of Jenner was required to overcome this feeling. He showed his tact when first called by telling his illustrious patient that he must with all due deference suggest that it would be mere waste of time for him to prescribe unless her Majesty made up her mind to implicity follow his instructions. Satisfied on this point he asked for several consultations on successive days and laid down rules of life which the Queen followed until her death. He insisted that she should take outdoor exercise, irrespective of weather, and should have not less than seven hours' sleep—eight if possible; that she should never sit in overheated rooms and that her diet should be as simple as the exigencies of her position permitted. Malt liquors and sweet and heavy wines were tabooed. Hence the Queen's favorite beverage was dry champagne, hock, moselle, and in later years old malt whisky and some effervescing water. When Jenner died her Majesty was greatly troubled, but she had at hand another physician, a Scotchman, Dr. James Reid, a pupil of Jenner's who was strongly recommended to the Queen by him. The Queen made Dr. Reid a baronet and showered other honors on him. He was always with the court whether at home or abroad, except for a brief autumn holiday. He married a maid of honor, the Hon. Susan Baring. He is now just over fifty and was resident physician to the Queen for thirty years. He is recognized as a "level-headed, shrewd, cautious and far-seeing man." He has no great faith in drugs, but believes more in hygiene. He is very reserved and there is one subject on which he has never been known to speak—

the health of his royal patient. This reticence no doubt has helped to secure his advancement at court.

A voluminous report on the recent outbreak of bubonic plague in Sydney has been issued by Dr. J. A. Thompson, president of the Board of Health of New South Wales. Between January 19 and August 9, 1900, 303 persons were attacked. The metropolitan area, which has an estimated population of 436,000, including about 4,000 Chinese and a few colored people, alone was affected. Two hundred and ninety-three whites and 10 Chinese were attacked. Four times as many males as females were affected. More than half the cases occurred between the ages of fifteen and thirty-five. There were 103 deaths. Haffkine's prophylactic serum was injected into 10,700 people, of whom 13 developed the plague, but recovered after mild attacks. The Yersin-Roux serum became available on May 13th, but its use did not interfere with the natural course of the epidemic. The following conclusions are drawn as to the mode of infection: (1) The disease was not directly communicated from the sick to the well; (2) it was not communicated—in any important degree, at all events—by mediate channels, such as clothes, household goods, merchandise or excreta; (3) the infection was attached to localities and spread to adjacent ones; (4) it also spread in a fashion which betokened the possibility of transport from a distant focus; (5) in an infected locality cases occurred irregularly in the buildings and showed no special proneness to occur in adjoining houses; (6) when one case occurred amongst the inhabitants of a building, secondary cases rarely followed. Irregularity of incidence on houses was thus accompanied by irregularity of incidence on the inmates; (7) an epizootic disease among rats preceded the first case in man; (8) this epizootic disease was plague; (9) the area over which the epizootic extended was practically coextensive with that in which cases of plague were observed; (10) the epidemic was caused by communication of the disease from rats. As to prevention, Dr. Thompson says: "The best protection against plague lies in sanitary laws persistently and faithfully executed by local authorities during the absence of the disease, and no other general scheme of defence is practicable." However, he lays great stress on the securing of immunity from rats—by preventing their landing and by building houses in such a way and keeping them in such a cleanly condition as to make it difficult for rats to enter or to live if they do enter.

House Physicians Get Out.—After a protracted meeting of the medical staff of the Orange Memorial Hospital and the Board of Managers, February 27th, the staff accepted the resignation of Dr. Frank H. Glazebrook and Dr. Henry P. Merrill, Jr., the two house physicians. The house physicians offered their resignations on Saturday, giving as a reason that they could not longer endure the dictation of the superintendent, Mrs. Mary J. Chambers.

CANCER AND THE BLOOD—TYPHOID PERFORATION—PENETRATING ABDOMINAL WOUNDS—CRANIECTOMY AND MENINGITIS—RADIOGRAPHY AND PROJECTILES IN THE FACE AND CRANIUM—APPENDICITIS—SPLENIC RUPTURE — PNEUMOTHORAX—CEPHALORACHIDEAN FLUID—POTT'S DISEASE OF THE SPINE.

Tuffier, at the Société de Chirurgie de Paris, January 9, 1901, said that examination of the blood in doubtful gastric disease is often of the greatest diagnostic importance; sometimes the diagnosis of cancer can be confirmed in the presence of other symptoms and sometimes suggested in their absence. Leucocytosis usually accompanies all forms of infections and is therefore apt to be present in gastric cancer, but unfortunately ulcer of the stomach, if complicated with some infection, will also often give this sign. He cited one case, in which the patient had presented many of the signs of a suppurative perinephritis for some time. A hemodiagnosis was a confirmation of this view, notwithstanding the fact that the temperature had declined. At the operation a large abscess was evacuated at the suspected site. He had also had two other patients in whom a hemodiagnosis was exceedingly valuable in ruling out suspected and in recognizing the actual disease. Hartmann said in the discussion that not only is a quantitative but also a qualitative leucocyte count necessary.

Loison, in discussing the subject of perforations during the course of enteric fever, said that the diagnosis rests on three facts, pain usually localized, complained of by the victim, a marked change in the temperature and a failing of the force of the pulse. He has in reviewing literature collected ninety records of surgical operation for the perforation. Seventy-four patients had perished. Of the sixteen recoveries, half occurred in the second or third week and the other half at a later period. Twelve of the interventions were done at the exact moment of perforation, the symptoms of which are exactly described. Ten of the operations were after an interval of about twenty-four hours. The results though not yet very good demonstrate that the treatment of intestinal perforation, at the time or later, is surgical. Hartmann, in the discussion, said that the more recent statistics in America were very hopeful of this condition as surgically treated and further showed that the more early and precise the diagnosis the better the prospect of success.

Rochard, at the meeting of January 16th, narrated the histories of three cases of penetrating wound of the abdomen in behalf of Anoray. Three others of the six of this author were published in full by him. The fourth was a fatal revolver wound in which surgical intervention had been undertaken too late. The fifth was a knife thrust into the abdomen. The laparotomy which was done at once showed only slight hemorrhage from the epiploon. Prompt and

complete recovery followed. The last case was also a stab, but laterally through the eighth intercostal space through the thorax into the abdomen. A lateral laparotomy showed a penetrating wound of the diaphragm filled with a small hernia of epiploon, another wound in the transverse colon. Both were sutured and recovery followed. In these cases Anoray contented himself with attention to the immediate field and did not eventrate the intestines. It appears that such a step should always be taken as a precaution. He also had some difficulty in suturing the diaphragmatic wound. Rochard said that the transpleural route is by all means best, because the pneumothorax which results is not troublesome. In dogs he has repeatedly demonstrated that it rapidly disappears.

Poirier presented an interesting case of fracture of the base of the skull complicated by late meningo-encephalitis and cured by wide craniectomy. While intoxicated the patient, a workingman, fell so that the right side of his head struck the ground. He arose and was able to walk home, into his house, but on the stairs reeled and had very severe hemorrhage from his nose and mouth, and loss of consciousness. He was taken to the hospital where three days later at evening an ecchymosis of the right conjunctiva was noted and later of the lids of that side. On the fifth day he thought himself able to return to work, but that afternoon he had to give up and return home on account of an unendurable headache. In the hospital it was suspected that a meningo-encephalitis had begun. Lumbar puncture obtained a turbid, slightly purulent and hemorrhagic fluid confirming the diagnosis. Operation upon the cranial vault was at once determined upon and on each side, with mallet and chisel, trap-doors about five by four centimeters were cut. When the dura was incised much fluid analogous to that from the spinal canal was obtained and other evidences of inflammation discovered. Good toilette of the field was made and efficient drainage established, but the precise site of the fracture was not seen. An entirely satisfactory recovery followed. The bacteriological examination of the fluid obtained in the lumbar puncture showed staphylococcus pyogenes aureus.

Tuffier in behalf of Mauclaire reported two cases of projectiles located in the head, especially about the face and cranial cavity. The apparatus of Contremoulin was employed. In the first patient the penetration was beneath the middle of the zygomatic arch and the bullet was located in and extracted from the orbital cavity. In the second patient the bullet had entered in the left temporal fossa and was recovered in that of the other side, where the radiograph plainly showed it to be. Tuffier himself has seven times succeeded easily with the apparatus of Contremoulin. Twice the bullets were extracranial and five times intracranial. Up to the present thirty-one cases are recorded in which it has been used. Twenty-eight were absolutely and three were partly correct. The field of use for this instrument is certainly wide.

Alluding to this subject Mignow, at the meeting of January 23d, gave the history of a man who three years before treatment had been shot with a pistol in the right side of the head. Since the wound irregular cerebral symptoms had supervened. Radioscopy located the ball exactly and without trouble, it was removed and complete cure followed. The diagnostic value of radiography in such cases is immense.

Poirier, in defence of the dictum that in the treatment of acute appendicitis it is necessary to operate just as soon as the diagnosis is established, cited his own and his assistants' statistics since 1899, a total of sixty-four cases. That year the number was twenty-six. Of these seven were in the interval, all recovered, and nineteen were in the attack with two deaths, although eight had a general peritonitis. In 1900 in hospital practice he had one interval and nineteen acme operations, without a death. In private practice he had eighteen operations, fourteen recoveries. At least some of the fatalities were ascribed to the disadvantages incident upon work in houses as compared with that in hospitals. Although capable of improvement, this record supports his contention.

Loison recited the following facts about a case of rupture of the spleen successfully treated by him. August 3, 1898, the man was kicked by a horse in the left side and soon afterward showed signs of visceral damage. Several of the ribs were broken and there were signs of a localized peritonitis pointing, through the subjective symptoms, to lesions of the colon and stomach. At the laparotomy these viscera with the spleen were exposed. Only the spleen was ruptured as shown by the active evacuation of old blood walled off by adhesions. The rent in the viscus did not seem to necessitate splenectomy, so the blood-flow was checked by tamponade. The ultimate outcome was most satisfactory. The patient was seen two years later (in July, 1900) and found to be in excellent health and without symptoms or signs pointing to the splenic damage.

Gaillard, at the Société Médicale des Hopitaux, January 11, 1900, stated that he had recently had a case of fetid pneumothorax which was cured by simple pleurotomy. The twenty-five-year-old woman, without any morbid history, a few days after childbirth was seized with violent pain in the side, cough, dyspnea and bloody expectoration and fetid breath and sputum. At the hospital it was found that she presented all the signs of a right pneumothorax localized on the postero-external aspect of the chest. Exploratory puncture obtained a small amount of hemorrhagic, fetid sero-pus, which contained no pneumococci. For a few days the course of the disease went well, when the onset of urgent signs made a surgical intervention advisable. A simple pleurotomy evacuated a large amount of foul gas, but hardly any fluid. The

urgent symptoms then disappeared, but the signs of the pneumothorax persisted with little change, although the subjective manifestations also improved. Nevertheless the general relief continued and after two months the woman returned to her vocation with only a few functional derangements, otherwise able to follow her duties.

Chauffard in the discussion said that the one point not clear in the case was the source of the fetid pus. He had an analogous case in which at the operation no source of the pus could be seen and at the autopsy it was found to be an interlobular encysted empyema. Very likely a similar localized focus had been the cause of the trouble here.

Monod, at the meeting of January 18, 1901, discussed the cellular elements found in the cephalorachidean fluid. Widal, Sicard and Ravout have recently explained the varieties they found in various inflammatory conditions of the meninges, especially the tuberculous forms. Monod had selected patients afflicted with tabes dorsalis and general paralysis. Upon centrifuging the products of lumbar puncture he found various varieties of cellular elements among which the lymphocyte predominated. Of such cells he had seen forty to fifty in the field of an oil immersion. Except in cases of acute and chronic inflammation he had never seen such cells before and he offered the opinion that the meninges react to disease in practically a constant manner of which these cells are a sign. Widal in the discussion said that he, too, with Sicard, had recently been examining the fluid taken from tabetics and paralytics. In such he had found great hordes of lymphocytes mingled with uninuclear cells. Such he had not yet seen in cases of chronic meningitis. For such researches the technic comprises the withdrawal by lumbar puncture of four cubic centimeters of the fluid, which are received at once into the tube and centrifuged at high speed. The supernatant fluid is then gradually decanted, leaving the deposit in as little fluid as possible. This is then taken up in capillary tubes and transferred to cover-slips where after careful spreading it is stained. The quantity of leucocytes may permit us to distinguish between tuberculous meningitis and acute cephalomeningitis, leptomeningitis and the majority of acute maladies which affect the membranes. Similarly the number of these lymphocytes in the fluid during the course of various organic nervous diseases seem to show only the involvement of the meninges and may, therefore, be of clinical advantage in diagnosing such invasion. Sicard said that he had examined the cerebrospinal fluid in four cases of meningomyelitis, three of syphilitic and one of unknown origin. In all were found numerous cellular elements whose characters were mainly mononuclear. These facts have the value of permitting the clinician during the life of the patient to examine into the condition of the meninges by such examinations.

Touche said it is essential to recognize in Pott's disease of the spine whether or not there is compression of the nerve-roots, when the disease occurs with a transverse myelitis. The prognosis of the paralysis is the element depending upon such diagnosis. This point cannot be arrived at either at the onset of the disease nor at the advent of the paraplegia by any study of motor and sensory signs. With the decline of the symptoms, however, we may concern ourselves with some satisfaction with the typical or atypical affections of sensation about the proper root area. The best signs, however, are the retention of urine and the state of the reflexes. The reflexes in different individuals seem to depend upon whether or not a pachymeningitis has traveled along certain roots. Hence we can ascertain practically the site and degree to which the roots are involved; especially when the sensory disturbances of the root area are investigated.

Rendu in the discussion said that in at least a certain number of cases paraplegia in the course of a spondylitis may be due to an extramedullary and extraradicular lesion. Its origin may be a small amount of pus which has worked its way into the spinal canal and there set up pressure effects. If it disappears the signs of the pressure also vanish and the paraplegia improves.

SOCIETY PROCEEDINGS

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held January 5, 1901.

The President, John B. Walker, M.D., in the Chair.

Suppurative Appendicitis.—The paper of the evening on this subject was read by Dr. Ramon Guiteras. He said that as soon as the inflammation in the appendix exhibits a tendency to the formation of pus, the treatment of the disease is surgical, not medical. If the pain and tenderness are not severe, the temperature not high, and the pulse reasonably good, an ice-bag may be employed during the first twenty-four hours. If the temperature and pulse become more normal the attack may be considered over for the time being. If on the third or fourth day of an attack there is still disturbance of temperature and pulse, the probability is that pus has been formed. By this time the spasmodically-contracted muscles have become tired and a lump may be felt in the right iliac region. At times the tumor may be felt at the first visit. The size of this tumor bears, as a rule, no relation to the length of time since the last attack, nor always to the severity of the symptoms in that attack. It may have existed for months and yet be no larger than a lemon, or, it may have existed only for weeks and be as

large as an adult head. If pus has formed there is always a septic temperature and the pulse is disturbed. When pus has formed, operation affords the only means of relief. At times small amounts of pus may be absorbed. However, the general rule is that, once pus has formed, rupture will inevitably take place sooner or later into the peritoneal cavity, or some of the hollow viscera, unless operation is done. The disappearance of the tumor is nearly always a bad sign. For the moment, the patient may have a sense of relief from the feeling of discomfort in the lower right abdomen, but tympanites soon follows and general peritonitis closes the scene. An appendiceal abscess may point on the skin and Nature cure the patient by this means. It is usually easier, however, for the pus to force its way into the peritoneal cavity. In one case, seen some years ago, drainage of a very large abscess was difficult, because the collection of pus extended down around the rectum. Septic pneumonia developed and the patient died. It seems probable that in these cases the abscess should be opened through the rectum, as this furnishes much better opportunity for thorough drainage.

Removal of Appendix.—Whenever it is possible the appendix should be removed at the time of operation. Especially is this true when there have been several recurring attacks of appendicitis. If the removal of the appendix requires considerable manipulation and the breaking up of many adhesions, it seems better merely to open the abscess at the time of the acute attack and to leave the removal of the appendix until a later operation can be done. This is, of course, a disputed question. There are good operators who insist that the appendix can always be found at the time of the primary operation and that its removal guarantees against recurrences. To leave the appendix, they say, invites recurrence. At times, when the appendicular abscess is small, there seems to be no reason to doubt that pus is absorbed. In some cases, in which there has been an acute attack with some septic temperature and pulse indicating the presence of pus and the acute symptoms have subsided under ordinary medical treatment, a later operation may show the presence of very little pus, practically none. In a recent case Dr. Guiteras found just a drop of greyish pus in a patient whose symptoms indicated some time before the existence of a considerable septic focus. The size of the tumor is not always an indication of the amount of pus. Its hardness may at times give rise to the suspicion of the presence of a sarcoma. In a recent case in which sarcoma had been diagnosed by others who saw the case previously, abnormalities of temperature seemed to point to a purulent condition. When the tumor was cut down upon dense tissues were found surrounding a small quantity of pus, not more than two or three drams.

Fallibility of McBurney's Point.—In the discussion Dr. Egbert H. Grandin said that recent experience has shown him that it seems to be a mistake to lay so much stress on the diagnostic value of McBurney's point. Localized pain and tenderness at that point often appear only at an advanced stage of the disease. If the general practitioner waits until these symptoms are present, and this he has been taught to do, his patient will often come to the surgeon too late. McBurney's point is of value, but it is not pathognomonic and tenderness in that spot does not exclude the existence of certain other pathological conditions. In two recent cases of extra-uterine pregnancy, under Dr. Grandin's care, there was distinct tenderness over McBurney's point. As a matter of fact, pain at this point is rather uncommon in an early stage of appendicitis. Pain occurs first at and around the umbilicus. It may often be referred to up under the liver, and therefore there is a suspicion of the presence of gall-stones. If the abscess exists behind the cecum the pain may be much farther back. When the appendix points downward from the cecum the pain may be much lower than McBurney's point. Appendicular abscess between the uterus and the bladder may give symptoms that simulate a number of gynecological conditions and the pain will be referred to the pelvic region. It must be remembered that appendicular abscesses lying close to the vagina may be readily opened and thoroughly drained through this canal.

Primary Operation Technic.—The less done beyond draining and washing out a large appendicular abscess, the better for the patient. The possibilities for harm, if adhesions are broken down and pus gains admittance to the general peritoneal cavity, can scarcely be overestimated. During the course of the drainage the appendix will often slough off and come away with the pus. This is as effectual as if it were painfully searched for and picked out of the adhesions in which it so often lies buried. When these adhesions are thick and considerable manipulations are needed to free the appendix, there is risk of rupturing the wall—a frequently-fatal accident. In many cases counter-drainage into the loin is extremely important. In women it is often feasible to make the counter-drainage through the vagina.

Removal of Appendix.—Dr. William B. Coley said that there is great difference of opinion, among those having the largest experience in the matter, as to whether the appendix should always be removed at the primary operation. Dr. John Deaver says that the appendix should always be removed. This is certainly good surgery in his skilful hands. But if followed as a general rule, the advice would be productive of many fatal results. If after a moderate search the appendix can be found, its removal is advisable. The patient's condition is of importance in this matter. If he is able to stand manipulation well, a longer search may be made. There is no doubt that the appendix

often sloughs off and comes away during the drainage. It does not always do this, however. Dr. Coley has seen a secondary appendicitis in a case in which the patient had been assured that the appendix had sloughed off and come away during a preceding surgical treatment for appendicitis. A good many patients have recurrences if the appendix is left. Hernia often follows the use of free drainage. In such patients secondary operation should be advised for the removal of the appendix and also for the radical cure of the hernia.

Iodine-Test for Pus.—Dr. Theodore Dunham said that his experience in the use of iodine for the staining of the white blood-cells seems to show that this test is of some value in deciding the presence or absence of pus. The leucocytosis in a case of appendicitis, if high, often makes the presence of pus absolutely certain. When, however, the leucocytosis is not sufficiently high to make assured differentiation between a purulent and a non-purulent condition, the iodine reaction may serve to confirm the diagnosis of the presence of pus. In a case of suspected abscess of the liver in a boy, Dr. Dunham was encouraged to operate because of the presence of the iodine reaction. Up to this the patient had been treated for typhoid fever. The liver was found to be swollen and an incision into it gave exit to a quantity of pus, after which the patient made a prompt recovery.

Leucocytosis in Appendicitis.—Dr. Potter said that a review of eighty cases of chronic appendicitis examined during the interval showed that while leucocytosis as a test for the presence of pus is of some value, it is not finally significative. Like every other single symptom—pain, fever, pulse—it is valuable confirmatory sign, but gives no absolute assurance. As one of a set of symptoms it adds considerably to the surgeon's assurance in a given case, but is not pathognonomic.

Dr. E. K. Dunham said that he was very much interested in the report of certain cases in which gas, as well as pus, was present. The bacillus aerogenes capsulatus is an almost constant inhabitant of the intestinal tract. It is from here, of course, that the bacteria find their way into the appendix, and it would be interesting to know how often these bacteria occur in the abscess and how often gas occurs in connection with appendiceal pus.

Dr. Edward M. Foote said that a recent remark from our friends the osteopaths with regard to the leucocytosis of appendicitis seemed of special interest, because of its supreme assumption. The osteopath by manipulation sets the spleen in vibration. This is claimed to cause the outwandering of a great many leucocytes into the circulation, and thus cures the infective process which is at work—according to the osteopath.

Value of McBurney's Sign.—Dr. John B. Walker said that McBurney's sign is not of absolute, but of relative diagnostic value in cases of appendicitis. When a collection of pus is retro-cecal then tenderness is not apt to exist at McBurney's point at all. The pain and tenderness are apt to be much more diffuse and there is usually very little tenderness in the center of the patient's abdomen. In these cases, too, the pulse and temperature are apt not to be so high as in other cases in which the abscess wall is so situated with regard to the general peritoneal cavity that there is opportunity for the absorption of more purulent toxins. There is no doubt that extra-uterine pregnancy simulates appendicitis by causing pain and tenderness in the region near McBurney's point. Abscess of the ovary may also produce pain and tenderness here as in a recent case under Dr. Walker's care. There are certain cases of appendicitis in which the pain occurs first in the epigastrium. At the beginning of the attack this is not very intense, but it may become very severe. In a recent case it was thought that rupture of the stomach or duodenum had taken place. Operation, however, revealed a gangrenous appendicitis. McBurney's symptom has its value, but must not be considered either pathognomonic or exclusive in its significance.

Dr. Reynold Wilcox said that the diagnostic significance of McBurney's sign is much overrated. In many cases it is useless and worse than useless. Its absence tempts the general practitioner to delay his diagnosis of appendicitis until the case has perhaps gone beyond the stage in which surgical intervention would be of benefit. In general it is a criterion that can not be depended on and of which too much has been made by text books and lecturers.

The True McBurney Sign.—Dr. W. B. Coley said it must be remembered that the symptom to which Dr. McBurney called attention is not pain but tenderness at a point midway between the umbilicus and the anterior superior spine. This sign is of very positive value as an element in diagnosis. It must not be considered the sole pathognomonic symptom, nor is its presence a sure indication that the underlying pathological condition is appendicitis. Taken in connection with other symptoms, however, it is a very valuable diagnostic factor. Tubal and ovarian disease especially may simulate the tenderness which occurs at McBurney's point so characteristically in the majority of appendix cases. As a rule, however, it is not difficult to differentiate these conditions from appendicitis at times when surgical intervention is not insistently called for and at other times the indications for surgical procedure retains its value.

Difficulties of Technic.—Dr. Ramon Guiteras said that at times considerable hemorrhage occurs from the walls of the incision made for opening an appendiceal abscess. This hemorrage comes from branches of the circumflex iliac artery which occasionally runs across the field of operation. The ends of the cut artery

should be caught as soon as its presence is noted and the ends either twisted, or, if necessary, a ligature applied. Extensive manipulation for the purpose of securing the appendix may easily lead to the opening of the general peritoneal cavity. Therefore it scarcely seems advisable, especially in cases of extensive abscess, or when the appendix can not readily be found.

Such a search involves much more risk for the patient than the presence of his appendix. There is no doubt that the appendix often sloughs away, for portions of it are not infrequently found in the drainage from the abscess. The direction in which the appendix points depents on the length and character of its mesenteric attachments. In perfectly normal individuals the appendix may point in any direction. As a general rule, however, it points toward the umbilicus and in all these cases ulceration in its neighborhood will cause pain and tenderness at McBurney's point.

Difficulties of Drainage.—In certain cases the cecum becomes pressed up beneath the incision and so prevents proper drainage. In these cases means must be taken to keep the cecum out of the way. If the cecum should become distended with gas, even to a slight extent, as happens not infrequently during convalescence from appendicitis operations, it will usually close up the drainage canal. It is advisable in some of these cases to insert a Mercier catheter in order to maintain drainage.

Dr. Lincoln reported a case of appendicitis in which the pain and tenderness and the tendency to abscess formation were found to be in the region of the kidney on the right side. This caused serious doubt as to the diagnosis. At the operation it was found that the cecum occupied a position just over the kidney as it does in fetal life. It was evident that by some error of development the cecum had never descended to its proper position, but maintained its original location.

Stated Meeting, Held January 25, 1901.

The President, John B. Walker, M.D., in the Chair.

Intestinal Plug.—Dr. Edward M. Foote presented an intestinal plug meant to be worn by patients who have an artificial anus. It consists of a solid plug of gutta-percha, about two inches and a half long and about three-fourths of an inch in diameter, surrounded by a rubber cushion in the shape of a ring containing air. This can be worn without any inconvenience. Its insertion in the rubber ring makes it reasonably capable of retaining all fecal material unless this be of very watery consistency, while at the same time it yields to every motion of the patient and can be worn without discomfort. It may be removed every four hours or so and the artificial anus thoroughly cleansed. Dr. Foote also exhibited a sigmoidoscope and a small electric lamp which could be used for its illumination. The electric battery for this lamp can easily be carried in the pocket. This enables one to make high examinations of the rectum and even of the beginning of the sigmoid at a patient's home without any necessity for transporting very cumbersome and expensive apparatus.

Obstruction from Enterolith.—Dr. Howard Lilienthal reported the following case: The patient, an old lady sixty-four years of age, was taken with severe abdominal pains after a Thanksgiving dinner. The pain was general in character and could not be localized distinctly. It grew worse and uncontrollable vomiting finally set in. There was more resistance to palpation and more tenderness in the right iliac region. Considerable tympanites developed and an operation seemed absolutely indicated. Exploratory laparotomy was advised. As soon as the abdominal muscles became relaxed a tumor in the region of the appendix could be made out. Appendicitis had been suspected before and now this diagnosis seemed confirmed. An incision was made as for the removal of the appendix. Adhesions were found to exist between the loops of the intestine and the cecum in this region and considerable free peritoneal fluid escaped through the incision. The cecum itself was found unaffected by any pathological condition in it, but the ileum not very far from its anastomosis with the large intestine contained a hard lump. This lump caused occlusion of the intestine so completely that below it the ileum was absolutely flaccid while above the intestine was immensely distended. An incision was made in the wall of the ileum and a stone over an inch in diameter was removed. Rapid recovery took place after the operation and no sequelæ of the condition have been noted.

Origin of Enterolith.—As is usual in the case of enteroliths this one seems to have been originally a gall-stone. The most careful investigation into the woman's history, however, fails to reveal any evidence of pain or fever, or jaundice, or intestinal disturbance, or even discomfort in the liver region, any time during life. This stone still bears on it a certain number of facets which show that it was not the only stone in the gall-bladder at the time that it was passed to the intestine. The passage of stones of such large size from the gall-bladder to the intestine without any symptoms remains one of the mysteries of intestinal pathology.

Resection of Epididymus.—With the idea of relieving a condition of sterility which had existed for some time, Dr. Lilienthal did a resection of the vas deferens and a transplantation from their point of origin to another part of the testicle. The patient was a man of forty who was normally fertile up to a year or two ago. Examination showed the presence of a series of nodules in the epididymus. These were considered to be tuberculous in origin. Seminal fluid

expressed from the seminal vesicles contained no spermatazoa. Samples of seminal fluid from the condom also showed the absence of zoosperms. With the idea of relieving the condition by an experimental operation, the vas deferens was opened and found to be perfectly free. A filiform could be passed into the seminal vesicles. An incision made into the globus minor of the epididymus with the expression of some fluid for microscopic examination seemed to show that there were no spermatazoa in this part of the genital apparatus. Some were found, however, to exist in the globus major. The vas deferens was then split and fastened by stitches to an incised portion of the globus major. The patient was able to leave the hospital in two weeks. So far there has been no opportunity of judging of his fertility. Spermatazoa have not been found in the seminal fluid. This is the first time that such an operation has been done, though its performance was suggested in White & Martin's Text Book on Venereal Diseases.

Gonorrheal Sterility.—Dr. Follen Cabot said that Dr. Lilienthal's operation opens up a vista of hope for gonorrheal patients who have suffered from double epididymitis. As is well known the inflammatory exudate in these cases completely closes the seminal ducts and as a rule the closure is permanent. This makes the patient absolutely sterile. As the patients are usually young men a condemnation to hopeless sterility through life makes an extremely sad condition. Therefore the possibility of relieving the sterility by the transplantation of the vas deferens opens up a new and very promising operative field in genito-urinary surgery. There seems no good reason why the operation should not be successful and Dr. Lilienthal's case will certainly be followed with a great deal of interest by genito-urinary surgeons throughout the country.

Torticollis Simulating Vertebral Dislocation.—Dr. Royal Whitman described a case which had recently been shown at one of the surgical societies as presenting a fracture or dislocation of the atlas or axis. The patient, a young man, was struck very severely on the jaw by a piece of wood in the hands of a drunken man. The resultant injury healed without much delay and the patient seemed to have completely recovered. Some weeks afterward a queer projection of bone was noticed at the back of the neck and a marked deformity of the head and neck resulted. It was concluded that a fracture of some of the cervical vertebræ existed. An X-ray photograph was taken and, while a fracture of the vertebræ could not be demonstrated, some disturbance of the relations of the atlas to the axis was found to exist. The condition was accompanied by intense muscular spasm which did not follow the accident immediately, but first began to develop more than a week later. The case proved to be one of simple torticollis in which the spasm of the muscles of the back of the neck caused the disturbance of the bony relations and the projection which simulated fracture or dislocation.

Orthopedic Treatment.—The patient was fitted with a jury-mast and the deformity was at once lessened. In a short time the pain also was relieved. It is not usually realized that severe torticollis may give rise to the deformity that occurred in this case. It is only when parts of the bones are emphasized by displacement due to spasmodic muscular action that it is realized how large the cervical vertebræ really are. These cases have become familiar to orthopedists in recent years, though they are still often sent to dispensaries or to specialists by the general practitioner with the idea that some serious pathological condition exists in the bones at the back of the neck. It is interesting to note that in this case a goiter has begun to develop. The spasm of the muscles forced the chin down upon the chest, thus interfering with the circulation to the thyroid gland and very possibly causing irritation to the tissue-element within the gland.

Spinal Cocainization in Selected Cases.—Dr. Gibson said that he had recently had a case in which the production of general anesthesia by the ordinary means seemed especially contraindicated. The patient was suffering from diabetic gangrene and amputation at the thigh was required for the condition. He was an elderly man with seriously-diseased kidneys and arteriosclerotic arteries. In general he was in as unsuitable a condition for anesthesia and operation as Dr. Gibson had ever seen. One-fifth of a grain of cocaine in a two-per-cent. solution was injected into the spinal canal. Absolute anesthesia resulted almost immediately and lasted, according to observations made, an hour and a half. The operation was terminated absolutely without pain in about half an hour. There was no nausea or head symptoms and no toxic reaction of any kind. The patient was given thirty grains of bromide, three hours before the operation to quiet restlessness and $^1/_{150}$ of a grain of hyoscin at the time of the operation. He left the hospital two weeks later with the stump firmly healed. One single rise of temperature occurred during the convalescence and this was due to a sore throat. This is one of the cases that one can not help but feel would surely have been "wiped out" by general anesthesia.

Favorable Experience.—Dr. Green said that in a recent case he had seen two injections of one-third of a grain each made into the spinal canal in order to produce anesthesia. The first injection produced anesthesia only to the knee. The second gave anesthesia well up to the thorax. In this case a fistula extending well up into the rectum was thoroughly opened. The patient was found to be suffering also from hemorrhoids and these were removed by the clamp and cautery. The operations lasted more than an hour altogether and good anesthesia was maintained during the whole time. Fourteen cases have been operated on under anesthesia by spinal cocainization in the City Hospital. There

has not been a single bad result of any kind. A number of operators are persuaded that in certain cases operation would surely have proved fatal had it been attempted under general anesthesia. Spinal cocainization seems destined to take its place as a distinct adjuvant to surgery in certain difficult cases in which general anesthesia is contra-indicated.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 7, 1901.

The President, Robert F. Weir, M.D., in the Chair.

Bust of Dr. Horace Green.—A bust of the late Dr. Horace Green made under the direction of Dr. Green's family, was presented to the Academy by Dr. D. B. St. John Roosa. Dr. Roosa said in part: The community at large is hardly aware of the debt of gratitude which they owe the physician. When, some time ago, a set of judges was picked out to decide the names which should be inscribed in the Hall of Fame that is now being built on one of the hills around New York, not one doctor was selected for a place on the Committee. The first fifty names that are to be inscribed on this roll of fame have been selected and there is not a single physician among them. Is it possible that the name of Ephraim McDowell, whose pioneer work in gynecology saved thousands of lives and untold human suffering, does not deserve a place on a roll of America's famous men? Is Marion Sims to be left out? Shall Morton, who discovered anesthesia, made modern surgery possible, and saved such a world of suffering to mankind, have no place? Do such men sink in importance below the inventors of sewing machines, the writers of literary essays, or the makers of political speeches? If the public neglects, at least brother doctors must not forget. Fame is empty at best.

"Can storied urn, or animated bust
Back to its mansion call the fleeting breath?
Can honor's voice provoke the silent dust,
Or flattery soothe the dull, cold ear of death?"

Dr. Green conferred a great benefit on the medical profession by his ground-breaking work in laryngology. Before the invention of the laryngoscope he divined conditions that existed as the basis of symptoms, succeeded in getting hints of confirmation even with the imperfect examination methods of his day, and laid the basis of scientific laryngology. He was far ahead of his time and was naturally misunderstood. His work met with great opposition, and his methods were decried and even his motives impugned at a stormy meeting of the Academy. While a deeply sensitive man, kindly and sympathetic, he was yet one of the strong characters that goes on with appointed work despite opposition. It is but proper, therefore, that we should have this memorial of him and we owe a debt of gratitude to the friends who have presented it. May it long prove a source of inspiration to the members of the Academy and to the medical profession in New York in its noble work for the relief of disease and suffering.

The scientific business of the evening was then taken up—the meeting of the Section on Obstetrics and Gynecology before the Academy. This consisted of a symposium on the subject of "Conservative Operations upon the Uterine Appendages."

Present Status.—Dr. J. Riddle Goffe said that when modern gynecology began to be extensively practised about fifteen years ago, the desire to operate carried the gynecologists too far. They removed tissues that were scarcely at all diseased, and sometimes even normal sexual organs were sacrificed in the hope that this would afford relief from reflex symptoms. After this stage the pendulum swung the other way, and of late it has seemed that too little removal of diseased tissue has been undertaken. There is a true conservatism that takes the middle path between the two extremes. When organs are slightly diseased only portions of them should be removed; they may be freed from constricting adhesions, they may be replaced in their proper position, and in general the patient's condition can be vastly improved without radical operation.

Technic of Conservative Operation.—The simplest method of doing conservative work is to open the posterior vaginal fornix. In this way adhesions may be broken up and drainage secured that will relieve most symptoms. In acute cases relief is afforded almost at once. In chronic cases improvement results especially from the better circulation that comes with freedom from adhesions. After this, if further operation seems necessary, a portion of the ovary may be removed, or degenerated cysts in the body of the ovary may be punctured. Puncture may be done with a tenaculum, or with a knife or scissors. Some operators always prefer the actual cautery. Others think that when the cautery is used the extent of damage done to ovarian tissue cannot be properly gauged. If part of the ovary is hopelessly diseased, it may be removed. The inflammatory reaction that results from operation on the ovary proves a source of stimulation to the remainder of the organ and instead of doing harm does good.

Ovarian Circulation.—Professor Clark of the University of Pennsylvania recently showed that the circulation of the ovary is marvelously well arranged, so as to furnish nutrition even to the smallest healthy portion of the organ, whenever the blood-supply to other parts is cut off. The ovarian artery does not go directly to the ovary, but to the uterus. From it a series of arterial arches penetrate the substance of the ovary, anastamosing very freely with each other in every part of the organ. The removal of any one part, therefore, does not interfere with the circulation of other parts. Usually the part of the ovary that has to be removed is that farthest distant from the hilum. It is at the periphery that exsection is easiest and

surest of success. After the exsection the cut portion is well covered with peritoneum and all rough surfaces are turned in so as to avoid the formation of adhesions. No matter where the incision is made the blood-supply will prove sufficient.

Tubal Operations.—There is for the tube the same arrangement of mesentery and of blood-supply as for the bowel. The blood-supply in the mesosalpinx can be quilted off without fear of producing gangrene in the portions of the tube that may be left. If it is the distal end of the tube that is affected it may be amputated. The tube should be slightly split at the cut end and then its mucous lining stitched to the peritoneum, as is done in circumcision, this keeps the tube open, makes the original caliber of the tube large at the end, and provides an oval opening into which the ova may find their way from the ovary and thus prevent absolute sterility. It is not always the distal end of the tube that is affected. Sometimes the purulent collection is walled off by adhesions in the uterine end of the tube, or is limited to the central portion. If the fimbriated end of the tube seems unaffected it may be preserved and inserted into the horn of the uterus, thus conserving fertility.

Transplantation of Ovary.—This operation has been undertaken with the idea of securing the preservation of the menstrual function and avoiding the shock of its sudden stoppage. This precocious menopause often proves a severe strain on the nervous system. The explanation of the fact that menstruation sometimes continues after a double ovariotomy seems to be that some small portion of the ovarian tissue has been left and that this suffices to produce the nervous reflexes that originate the menstrual flow. This explanation seems much more probable than that of the existence of a problematic third ovary. Ovarian tissue when transplanted to another site often recovers its circulation and produces the usual reflex of the normal organ. The performance of this operation is thoroughly justified and there are possibilities in the way of subsequent fertility. The success of transplantation of ovarian tissue has given rise to the idea of transplanting the ovary of one woman into another. This has been done recently with a certain amount of success. No cases of pregnancy have occurred as yet, but it remains to be seen whether this procedure may not be justified even by the hopeful tinge that it gives to a young woman's life that is otherwise sexually eclipsed.

Gynecological Conservatism.—Dr. W. M. Polk said that conservatism in surgery has become the keynote of modern advance. Gynecology is not behind her sister specialties in the matter of the preservation of all useful tissues. It is the fear that one may be trifling with the life of a patient rather than any overweaning desire for the removal of tissue, that prompts the want of conservatism on the part of gynecologists. After all, life is preferable to any mere function of life. Radical operations, however, have not always given the relief from symtoms that was promised. The important thing to know is what are the proper limits of conservatism. The destruction of the tissues in the pelvis, as everywhere else, is proportionate to the virulence of the infection. There are two principal infectious factors—sepsis and specific infection. Under sepsis is included all the pathological processes which follow conception and parturition. The main specific infection is of gonorrheal origin. In any case an early outlet for the products of infectious processes mitigates the damage done. Hence the first step in conservative gynecology is free incision of the cul-de-sac of Douglas, thus affording a vent for infectious products and drainage that prevents further accumulation. If this were done early enough it would preserve pelvic tissues from ultimate destruction.

Accessory Operations.—If in infectious processes in the pelvis a large flabby uterus is found this will be benefited by the thorough application of the curette. In pyosalpinx the process is always a prolonged one. Usually patients do not come to the surgeon until the condition has been going on for several months. If the case comes early enough amputation may prove successful in completely removing the focus of infection. Of course the virulence of the infection is important. Muco-pus may be allowed to take care of itself. Pus will require, however, thorough drainage and the prognosis of ultimate success in securing function of the tube is dubious. The treatment of cysts constitutes an important problem. Some cysts will take on pathological development that will require subsequent operation. Most of them will remain absolutely without producing any untoward effect.

Age Limit of Conservative Operations.—When there is any hesitation conservatism should be the rule unless the patient is near the age limit, that is, over forty-two. The sexual function is extremely important for the happiness of the individual and especially for those in contact with her. This gynecologists and neurologists are in a position to know better than anyone else. Relief is not always afforded by radical operation and when even a portion of the ovary remains there is always the hope of maternity to brighten the life of the patient. This justifies plastic operations upon the ovaries and tubes. Success in this line will lift from gynecology the stigma under which it has so long labored of doing mutilating, rather than helpful work.

The Immediate and Remote Results of 156 Cases of Conservative Operations Upon the Uterine Appendages.—This was the title of a paper read by Dr. W. L. Burrage of Boston, Mass. This paper will appear in a subsequent issue of the Medical News.

Conservative Surgery in 182 Cases.—Dr. A. P. Dudley of New York detailed his experience in 182 cases. Six of them he did not consider conservative when done, but the menses have continued and the operation, therefore, was as radical as was intended. Dr. Dudley considers that there is much more danger in conservatism

than in routine radical gynecology. The surgeon is often called upon to decide on the spur of the moment as to whether he has to deal with a septic or a non-virulent condition and on this decision may depend the life of the patient. The circulation has all to do with the success of conservative operations. This is usually interfered with by the pathological process which has been at work. Conservative surgery, far from increasing the circulatory interference, rather lessens it. In so important an organ as the ovary Nature can be trusted to restore the circulation, if she be but given half a show. Operation often helps her in this.

Cystic Ovaries.—Dr. Dudley prefers not to use the cautery in opening cysts of the ovary, although it is used extensively in France and Germany. There seems no doubt that it is more effective than simple puncture in preventing the recurrence of the cysts. How far the action of the heat destroys tissues beyond the points of actual contact is not known. There is no doubt that the cautery destroys many ova that lie around the cyst. This is an important consideration in conservative gynecology. There is no doubt in Dr. Dudley's mind that tubes once closed may become patent again. Years ago he used strong silk to tie off a tube and in a subsequent operation, months after, finding the silk still present he removed it. The patient's other tube had been removed and when some months later she became pregnant there was no doubt that the first tube, though crushed by the ligature, had yet somehow become open again. The tube is assisted in preserving its lumen free by the diaphragmatic suction action which draws liquid from the abdominal cavity into the tube. This suction action of diaphragmatic motion is not generally understood. Any operator who opens an abdominal cavity a few days before menstruation is due will find in it a couple of ounces of bloody serum. This is pumped out during the menstruation through the tube, by the action of the diaphragm. This serum will not be found to occur in the abdomen after menstruation.

BOOK REVIEWS.

A Text-Book of Pathology. By Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Philadelphia Hospital. Third Edition. 1900. W. B. Saunders & Company, Philadelphia and London.

Considerable diversity of opinion will exist for some time yet among both pathologists and clinical teachers as to the best point of view from which to present the subject of pathology to students of medicine. Some, particularly the more philosophical of pathologists, mindful alone of the theme as biological, will pass rather lightly by the morphological aspects to lay stress upon some of the large and far-reaching fundaments governing cellular activity. To them the problems of disease present themselves as the physiology of cell life in the broadest sense. Another group of writers, looking at pathology from a wholly different aspect, has endeavored to correlate from the aspect of practice the morphologic findings of the autopsy with the clinical features of disease. For our own part the former alone embodies the true science of the subject, and the ideal will only find realization along these paths of interpretation. From this ground no book of pathology has been yet attempted; gleanings of this attitude are only derived now and then in monographic discussions. But it it to be hoped that the near future may number among its best scientific achievements just such a product of a newer outlook.

Of those books based on the traditional lines of treatment Dr. Stengel's book has been accepted as ranking among the best, especially in so far as the wants of most students and practitioners have been anticipated. Pathology is here the story of the physician of a younger generation. Beginning with the subject of causes, in a general way, to their general expressions, physiological and morphological, the author then takes up that great series of changes designated as inflammation. Here we confess disappointment. Inflammation has been so intelligently presented from the comparative viewpoint of the biological pathologist by Professor Adami in Allbutt's System of Medicine that the very inconsequential description of this theme here is a keen disappointment. The wide significance of inflammation is too important to be lightly dealt with; after all it constitutes the greater part of disease processes.

The general excellence of the section on bacteria will be appreciated by many. The classification of Migula has been followed. A few slips scarcely noteworthy enough to be mentioned have been detected here and there. Thus Koch is stated to have discovered the tubercle bacillus in 1880; as a matter of fact this investigator's first announcement was made before the Physiological Society of Berlin on March 24th, 1882. Other errors might be pointed out, but are really too subordinate to detract from the favorable impression on reading this section. In Part II. the special pathology is discussed; the accounts of the lesions are short and usually to the point. The revision of the sections on neuropathology has been carried out with uniform success by Dr. Joseph Sailer. On the whole this has been found sound and consistent. The mechanical part of the book is excellent.

As a book for undergraduate students or physicians at large Dr. Stengel's work will be found a safe and generally reliable guide to pathological morphology.

Enteroclysis, Hypodermoclysis and Infusion. By Robert Coleman Kemp, M.D., New York. James T. Dougherty, New York.

It is being recognized more clearly every year that the practitioner has a ready means of influenc-

ing diseased conditions in modifying the composition of the blood by the introduction of a diluent into the circulation. The rationale, the methods and the objects to be gained are all well discussed in this excellent small manual.

There has been a need for such a treatise and the present one can be commended as pertinent and as practical. The chapters on Intestinal Irrigation are of special interest, as are also those dealing with the application of dry heat or cold in the rectum.

Dr. R. H. Dawbarn of New York has contributed able chapters on Shock and Its Treatment and Anesthesia and Its Relations to Shock. For the many inquirers as to the proper procedures to be followed in the application of carbonated baths (Nauheim at Home) the very excellent chapter in Dr. Kemp's book will suffice.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By Various Writers. A New Edition, Completely Revised and Rewritten. Edited by Albert H. Buer, M.D., New York City. Vol. I., Aac-Bla. William Wood & Company.

Medical science is to be enriched by a second edition of this excellent work. It would be an impossibility to point out the various excellent features of this new revision, for in every sense of the word it is a revision, thoroughly modern and for the most part rewritten from the standpoint of the medicine of the last decade of the twentieth century. The work, moreover, is better illustrated than the first edition.

The work is a veritable *index-rerum* of medicine and should enjoy a wide sale.

A Manual of Syphilis and the Venereal Diseases. By James Nevins Hyde, A.M., M.D., and Frank Hugh Montgomery, M.D. Second Edition. W. B. Saunders & Company, Philadelphia.

In this, the second, edition of this excellent manual the reviewer is forcibly and favorably impressed with the wealth of illustration, when compared with the earlier edition. This increased illustrative feature, in a work which is so markedly descriptive, gives it at once a value to the practitioner which no amount of descriptive language could impart. With it as a guide there is no excuse for the confounding of the venereal disorders which are distinctive. It would be too much to hope that any work could make the practitioner infallible, but it may be said that this volume presents very attractive and praiseworthy features.

Twentieth Century Practice. Edited by Thomas L. Stedman, M.D., of New York. Vol. XX. Tuberculosis, Yellow Fever and Miscellany. William Wood & Company.

With this volume Dr. Stedman has brought to a successful termination his monumental task of giving the American medical public its first extensive series of monographic treatises which are not system translations. Apart from all other considerations the editor is to be congratulated on the good work accomplished.

This present volume is intrinsically an interesting one. The subject of tuberculosis alone makes it an important volume in the series. The opening chapter, on the Bacteriology, Pathology and Etiology of Tuberculosis, by Dr. A. J. Lartigau, for conciseness, logical mode of treatment and pedagogic application, is one of the best known to us, and much the same praise is to be bestowed on the chapter by Dr. S. A. Knopf on the Diagnosis, Prognosis, Prophylaxis and Treatment. On the contrary, however, the articles on Yellow Fever and on Mushroom Poisoning are inadequate, and far from modern. The chapter on diseases of the Uvula, Fauces, etc., by Dr. J. E. Newcomb, and that on the Mental and Neural Diseases of Children are excellent.

Practical Gynecology. A Comprehensive Textbook for Students and Physicians. By Dr. E. E. Montgomery, Professor of Gynecology, Jefferson Medical College. P. Blakiston's Son & Co., Philadelphia.

Of the making of books there is no end, but if they were all as good as this one the reviewer would derive much pleasure from his onerous duties.

It is practically impossible to give the necessary space in our columns in order that a correct appreciation of the volume before us might be given, but it may be said in short that we believe this to be one of the very best treatises of its kind. It is not a small book; there are 800 pages, and hence it cannot be slipped in the pocket for ready reference, but we believe that it is an invaluable work for every practitioner who is trying to perfect himself in gynecological work, both diagnostic and operative.

The work is beautifully illustrated, largely from half-tone plates of photographs of the actual conditions, and the generally recognized high class work of the publisher needs no comment.

Diseases of the Nervous System. A Text-Book for Students and Practitioners of Medicine. By H. Oppenheim, M.D., Professor at the University of Berlin. Authorized Translation by Edward E. Mayer, A.M., M.D. J. B. Lippincott Company.

To neurologists Oppenheim's treatise is favorably and extensively known, and non-German-reading practitioners may be assured in finding this work thoroughly modern and valuable. It does not depart in its general scope from many of the more recent text-books on the subject, but it bears throughout the impress of the author's rich personal experience. Perhaps the most important advance that is to be noted in Oppenheim's book is the frank admission of a section on diseases of the sympathetic nervous system. While such a recognition is not a new conception, he has, perhaps, extended the lines more widely than other writers known to the English-speaking readers. For this alone, the work is especially valuable.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, MARCH 9, 1901. NO. 10.

ORIGINAL ARTICLES.

OUR DUTIES TOWARD THE CONSUMPTIVE POOR.[1]

BY S. A. KNOPF, M.D.,
OF NEW YORK.

"CONSUMPTION is a disease which has claimed more victims than all the wars and all the plagues and scourges of the human race. Even in the few short years since Koch's discovery, over 2,000,000 persons on this continent have succumbed to the fatal infection. In the last two decades in Cincinnati, out of a total mortality of 119,089 there have been 17,353 deaths from this dread disease. The annual tribute of the United States to this scourge is over 100,000 inhabitants. Each year the world yields up 1,095,000, each day 3,000, each minute two of its people, as a sacrifice to this plague. Of the 70,000,000 individuals now peopling the United States, 10,000,000 must inevitably die of this disease if the present ratio is kept up."

These were the impressive words of my distinguished confrère, Dr. Geo. F. Keene, of Rhode Island, at one of the recent meetings of the National Conference of Charities and Correction. Our own city, according to the estimate of Dr. Herman M. Biggs, has constantly at least 30,000 cases of consumption, and of these more than 15,000 are harbored in our worst tenement districts. Please do not consider me an alarmist when I tell you that a vast majority of them will die just at an age when they should be breadwinners and useful citizens. Statistics show that the death-rate of consumption is largest between the ages of seventeen and thirty-five. I have said that a vast majority of these 15,000 consumptive poor of our city will die, but this will not take place until they have spread the germs of their disease broadcast, and endangered the lives of many of their fellowmen, rich and poor alike, in short, of all with whom they may have come in prolonged contact.

Nevertheless, consumption is an eminently preventible and curable disease. It is curable in nearly all climes, not only in California and Colorado, but also in New York and New England. All that is needed for the treatment of consumption is relatively good and pure air, good food and plenty of it, the best hygienic and sanitary conditions, and willingness on the part of the patient to submit himself to the constant guidance of his physician.

You may ask, "If consumption can be prevented and cured, why do physicians let these people die?" My answer is: Consumption is not merely a medical, but also a social disease. Society must come to the aid of the physician; he alone cannot cope with this affliction. If society, if our wealthy citizens, if the many noble men and women, willing and able to help, could only know the life-history of some of these consumptive poor, they would realize what I mean by saying consumption is a social disease, and they would at once see where their duties lie.

Will you pardon me if I give you the history of two people, a man and a woman, two consumptive patients whose medical adviser I was for a short time. The story of the man I have told once before, last year, on a cold February night, when a few people had ventured out to visit the tenement-house exhibition and incidentally, were willing to listen to a little talk for which the Committee on Lectures had booked me. My subject was "Tenements and Tuberculosis." I described to my small audience that night my first visit to this man, and, since I learned his story on that occasion, you will permit me to relate it here as I related it there. From this description you will also learn what it really means to be a poor consumptive, living in one of our average tenement-houses.

I beg you to follow me in imagination on this visit. We have left our comfortable homes and arrived in the tenement districts where the other half lives. We pass the throng in the narrow street, make our way through the crowds of children playing on the sidewalk, and enter the dark hallway. The first thing that greets us is the odor peculiar to badly-housed humanity. You cannot define it, but those of you who occasionally labor among the poor know it only too well. Have you ever thought what this odor really means? It represents the exhalations of a multitude of people, the toxic products expelled during the process of expiration, which settle on the walls, ceiling, and stairs of these hallways. Chemistry has not yet been able to fix its composition; we know it exists and we know its deleterious influence on the individual who is obliged to live constantly in such a house. Some very prosaic people call this smell "the smell of humanity," or "the smell of poverty." I do not quite like these names, for I think them neither appropriate nor just. There can be humanity without smell, and amidst poverty there can be the sweet atmosphere of cleanliness and purity. If the bad odor we perceive in our wanderings through those dark halls must have a name, let us call it the smell of ignorance and greed. It is the result of ignorance on the part of the poor housed there, and who do not know the value of fresh

[1] Address delivered by invitation before a gathering of ladies, on January 30th, at the home of Mrs. S. M. Jarvis, 1 West 72d Street, in the interest of the Stony Wolde Sanatorium, an institution which has for its purpose the care of working-girls, poor young married women and children, suffering from tuberculosis.

air, sunlight, and the cleansing property of water—the trinity which, in combination, are the best antitoxin against those poisonous products. It is the result of greed on the part of the owner, for only a heartless man could tolerate such a condition of filth, foul air and darkness, as is characteristic of these tenement halls.

We ascend a few flights of stairs. Owing to the expense of artificial lighting, these halls are, of course, very dark, and, though we cannot see the dirt on the balustrades, we feel that it is there and only reluctantly take hold of them in order not to fall. We arrive at the rooms we are seeking. A knock at the door, a feeble invitation to come in, and we are in the midst of tuberculosis. There are two or three small rooms, but only one receives direct air and light. In a dark, small bedroom lies the patient; there is a different odor in this room, a distinct smell of disease mingled with the odor of cooking. We ask to have a window open, but the patient fears the draft. He is a husband and the father of six children, of whom two have died within the last year. The youngest of the remaining children is a few months old; the oldest, a girl of ten, attends to the household duties while the mother goes out to work. We greet our consumptive friend lying there, bid him cheer, and tell him that we have come to see what can be done for him. He faintly smiles and we ask him to tell his story. In a feeble voice, interrupted by fits of coughing, he tells us that up to two years ago he was a strong and vigorous man; he had a good position as a mechanic, lived in a better tenement than now, and drank only occasionally when life at home became too dull. Once he caught a severe cold. He went to a doctor. A few weeks of rest and some medicine and he got well. After some months another cold—the same treatment, the same result. And then again a cold, and so on, until the periods between the times when he could labor and earn became longer and longer. The savings from better times disappeared gradually; a cheaper tenement was sought; the visits to the doctor were given up, and the patient finally ceased to work altogether. To go to the dispensary was too much of an exertion. The faithful wife nursed him tenderly, but soon all the savings were gone. The burial of the two little ones—one having died of bowel complaint and the other of brain trouble—had cost so much that the mother decided to go out to work in order to support the family.

While listening to the pitiful story we look around the scantily-furnished rooms. The babies are playing on the dirty floor, touching everything with their little hands, putting their fingers in their mouths, and inhaling the dust laden with disease germs. When we consider that this case had only been reported a few weeks before, and that until then the patient had never exercised any care with regard to his expectoration, can we wonder that two of the children died within a few months, one from bowel complaint—which probably was nothing else than intestinal tuberculosis—and the other from brain trouble, which is only another name for tuberculous meningitis. The remaining little ones look pale and underfed. The little mother preparing the evening meal has seemingly a better appearance. She has to do so much running out in the street, to buy the provisions for the family that she gets more air, and if the father does not feel too badly she takes the baby out sometimes. Yet to the experienced eye there are already traces of overwork in this delicate child organism. The precautions the patient takes now with his expectoration consist in having placed before him on the floor a cuspidor partially filled with some antiseptic fluid. Owing to his weakness, he does not always succeed in depositing his sputum exactly in the center and sometimes he even fails to deposit it in the vessel at all. We call his attention to this lack of precaution and advise him to use a light mug which he can bring near to his mouth, or moist rags, which he should have burned in the evening on his wife's return.

Let us bid adieu to this unfortunate man for a moment, and let me speak to you of the case of a woman belonging to the class which you desire to help, for the benefit of which you have gathered here this afternoon and in the interest of which I have the honor to address you. A young person, a forewoman in a dressmaking establishment in one of our large department stores, presented herself to me for examination of her lungs. She had been ailing for nearly two years. I found her approaching the third stage of consumption, and yet she was working daily from half-past eight in the morning to half-past six in the evening; and when business was very brisk she stayed longer. This woman had been treated by several physicians and good physicians, but she did not improve. She came to me thinking I could do better, but I could not, and I will tell you why none of us succeeded in even bettering the condition of this poor woman. She could not, or would not entertain the thought of giving up work. Was she not the main support of the family, an old father and mother and some younger sisters, of whom only one earned a little as her assistant in the store? This devoted daughter and self-sacrificing sister was willing to take any kind of medicine, even follow my directions for better and richer food, but leave her work to spend all day outdoors in the open air, doing nothing, earning nothing, while her loved ones probably suffered from want, never! The story is a short one, but one of the saddest in my experience among the consumptive poor. It is pathetic to see such a noble-minded, large-hearted working-girl die because she would not cease working for those she loved. I was not spared seeing the last act of this drama. The younger sister, the assistant in the store, who was much attached to our heroine and almost her constant companion, presented herself likewise to me for examination. She too had contracted the disease, and at the time I saw her the tuberculous process had already made great inroads.

You have united here to save as many of such noble-hearted but unfortunate working girls as you can. You know as well as I do that if you could have taken that older sister in time to your sanatorium for treatment and could have kept her there for six or nine months, she would as an incipient consumptive, have had seventy to eighty out of a hundred chances of being cured, and lastingly cured. Could you have comforted her in her anxiety about parents and sisters by telling her: "Don't worry, child, while you are with us we will also see to it that your parents and sisters shall not be in want," she would gladly have stayed in the sanatorium, followed implicitly the directions for cure, would only too willingly have devoted all her time to getting well, and the peace of mind, created by your care of her loved ones, would have added to her chances for recovery.

In the sanatorium, which is not only a healing institution, but also a school of hygiene, she would have learned from actual experience how to take care of her expectoration, how to protect others from infection and herself from reinfection, what to do and what not to do in order to get well and remain well. Ten to one, with such knowledge and training taken home with her, into the modest dwelling of her parents, that young sanatorium patient would have been a hygienic factor in the family, and the younger sister would probably never have contracted the disease.

The task which you have set yourselves is not an easy one. As I have endeavored to show you, occasions will arise when you will have to support a whole family for months in order to save the life of a single working-girl. You will need much money, much sympathy, and much goodwill to do the work as you would like to do it, and as I wish you may be able to do it. But of the greatness of the work you are about to do, I venture to say that even you yourselves have but a faint idea. Every girl you take into your institution means the suppression of a center of infection. It is very often the pulmonary invalid in the earlier stages of the disease, when he or she is still up and about, working every day and helping to support the family, who constitutes a veritable danger to friends and relatives and also to the community. It is this class of consumptives, which, from either ignorance or carelessness, spread their disease broadcast by depositing their infections sputum everywhere without any regard to the danger. A careless or ignorant expectorating consumptive can eliminate and distribute seven billions of bacilli in twenty-four hours. You know that the expectoration of a consumptive, when allowed to dry and become pulverized, may, when inhaled with the dust of the atmosphere, cause tuberculosis. Predisposed individuals, naturally weak persons, or those who have just recovered from diseases like typhoid fever, pneumonia, scarlatina, smallpox, or grip, are particularly susceptible to contracting the disease. Thus, it is beyond calculation how many useful lives you may save by taking care of and curing one consumptive working-girl.

To expect the State or city alone to cope with the tuberculosis problem is unreasonable. The one State sanatorium, which we hope to have in our Empire State ere long, even could it accommodate a thousand patients, would only be like "a drop of relief in an ocean of woe." I fervently hope that the State will never have a sanatorium of that size, and I know that those who counsel our State authorities in this matter will never permit so large an aggregation of consumptives in one place. What are needed are multiple sanatoria and special hospitals of moderate size, located near the large centers of population. Our own State and city should have several of these, and private philanthropy will create more. There must be institutions which receive men, women and children suffering from tuberculosis, not only for the very poor classes, but also for people of moderate means. There are many people among consumptives who are too proud to enter an entirely free institution; they are willing and able to pay something and do not wish to feel that they are objects of charity.

The sanatoria situated at a greater distance from the city should receive, as far as practicable, the incipient and more hopeful cases. The special hospitals situated in the outskirts of the city should be as much for the purpose of isolation as for treatment. Such a patient as I described to you in our visit to the tenement-house should not be allowed to remain in the surroundings in which we found him. He is not only a danger to his family, but he may even infect the rooms in which he lives to such an extent that whoever happens to live in them after his demise may also contract a tuberculous disease.

You have my most heartfelt wishes for success. A nobler work you could not have undertaken. By creating an institution such as you have in mind, you will save many good and useful lives among working-girls and women. Your sanatorium will be the house of hope to many for whom there is nothing but despair at this moment.

16 West Ninety-fifth Street.

THE INTRAVESICAL EVIDENCES OF PERIVESICAL INFLAMMATORY PROCESSES IN THE FEMALE.

BY FREDERIC BIERHOFF, M.D.,
OF NEW YORK.

When, thanks to the kindness of my friend and colleague, Dr. R. Knorr, of Berlin, Germany, I was enabled to examine and cystoscope those of his clinical patients who presented symptoms referable to vesical changes, I was early struck by a condition which seemed to me, on first examination, to be a change similar to, if not identical with *cystite à colonnes*. Further examination of

the cases, however, convinced me that this view was erroneous, as the changes were invariably confined to *limited portions* of the bladder-wall, and as they occurred in patients who presented absolutely no obstruction to, nor difficulty in urination, as must precede the formation of *vessie à colonnes* (that, therefore, an hypertrophy of the muscular coat of the bladder might be excluded), but who had, in the majority of the cases, at some previous period, suffered from a parametritis, or allied conditions.

Upon calling the attention of Dr. Knorr to the subject, he suggested that we examine, whenever possible, all those cases giving a previous history of parametritis, perimetritis, or old malpositions, whether or no they presented vesical symptoms. This was, therefore, done, with the following result: Total number of cases examined, 443; history of parametritis, perimetritis, etc., obtainable in 214; symptoms referable to the urinary organs present in 264; "pericystitic strands" present in 136; no other discoverable cause for symptoms than perivesical changes in 8; perivesical changes, as accessory cause, in 67.

In cases of perivesical inflammation, the cystoscopic picture varies according to whether the pelvic inflammatory process is a recent, or an old one, and whether it has extended to and involved the bladder-wall, or only the adjacent tissues. If the process is recent, the exudate encroaches to a greater or less extent upon the bladder, the distensibility of which is, to a corresponding degree, impaired. If the exudate is unilateral, the excursions of the cystoscope are limited on the affected side, while normally free on the unaffected one. Similarly, if it occupies Douglas' cul-de-sac, the uterus tends to be somewhat displaced forward, and the excursions are limited toward the posterior wall of the bladder. In all these cases, if the amount of exudation is marked, the bladder-wall will be seen to bulge inward over the site of the exudate. When an inflammatory process in the tissues adjacent to the bladder extends to and involves the wall of this viscus (frequently an accompaniment of salpingitis and perisalpingitis), we at times meet with "œdema bullosum."[1]

When the process is an old one, and the exudate has gone on to organization, the cystoscopic picture is an entirely different one. In the same way that displacements of the uterus and adnexa may be caused by the traction of the fibrous strands, resulting from the organization and contraction of an inflammatory exudate, we may have the bladder affected by these strands pulling upon parts of its wall. But, while in the case of the uterus and adnexa, we get *displacements*, in the case of the bladder there is *distortion*. The most characteristic appearance, however, in these cases, is the presence, over *parts* of the bladder-wall, of sharp, scar-like formations, which rise, to a greater or less extent, above the surrounding wall, have a yellowish-white color, and tend to fimbriate at the ends. The parts usually affected are the lower lateral and the upper posterior and postero-lateral portions of the bladder.

Two conditions are to be differentiated from the "pericystitic strands." These are columnar bladder and the contractions of the muscular coat of the bladder. Of these the former is found only when some obstruction to the outflow of

Fig. 1.

"Pericystic strands"; mild degree of development.

urine has existed for some time, and has led, as a consequence, to hypertrophy of the bladder-muscle. The obstruction may be mechanical (foreign body, marked prolapse, tumors), or spastic, as in the early stage of tabes.[1] When this condition is present, the *whole* of the bladder-wall is involved in the hypertrophic process. It will be seen that the wall is crossed by a network of projections above the surface. These projections appear to anastomose, or to cross each other freely. They are of rounded contour. The

Fig. 2.

"Pericystic strands"; marked degree of development.

"pericystitic strands" are, as before stated, limited to certain *circumscribed portions* of the bladder-wall, rise, as a rule, less markedly above the surface, tend to have fimbriated extremities, and are of *sharp* contour. The contractions of the bladder-muscle are easily excluded, for, when they occur, we see the muscle-bundles appear and then disappear, over the entire field of vision, with the contraction and relaxation of the bladder-wall.

Bierhoff, Oedema Bullosum Vesicae.—Medical News, Nov. 24, 1900.

[1] Bierhoff, Dermatologisches Centralblatt, Vol. III., No. 8.

The prognosis of the recent condition is that of the exudative inflammatory processes themselves. The later changes are of interest chiefly because they may exert an influence as complicating factors in disturbances of urination, especially as an accompaniment, or additional cause of vesical hyperesthesia.

Treatment of the recent processes usually results in the disappearance of the vesical changes, although further involvement, with perforation of pelvic abscesses into the bladder-cavity, may occur. In the older cases, where the afore-mentioned strands are present, the prognosis, as regards the disappearance of urinary symptoms, is excellent. With regard to the full resorption of the strands, it must still remain an open question.

The treatment of the recent cases resolves itself into measures to relieve the underlying cause, and later to promote resorption of the inflammatory exudation. In those in which the strands

Fig. 3.

"Vessie à colonnes," with diverticulum, in a female.

are present, it consists of treating, first, of any inflammatory vesical changes, and, later, gradual distention of the bladder. The last-mentioned procedure, which gave us excellent results in a number of cases, is employed as follows: By means of a graduated syringe, a quantity of some indifferent fluid (boiled water, or boric-acid solution) is gently injected into the bladder, to the extent of its tolerance, and allowed to remain there for some minutes. It is then allowed to flow off until but a small quantity remains. On the following days gradually-increasing quantities are similarly injected, until, after a length of time which varies according to the extent of involvement and the elasticity of the strands, the bladder tolerates the normal amount of fluid. In this way we were enabled to remove entirely all vesical irritability, and, in several instances, to bring about a disappearance of the strands themselves.

Consumptive Hospital.—At the regular monthly meeting of the Citizens' Committee for the erection of a consumptive hospital, in this city, the Secretary made a report of having received several donations for February, so that the total amount received at the present time is $20,842.

THE PREVENTION OF INSANITY.[1]

BY HENRY WALDO COE, M.D.,
OF PORTLAND, OREGON;
MEDICAL DIRECTOR OF THE MT. TABOR NERVOUS SANITARIUM; CONSULTING ALIENIST TO THE OREGON STATE INSANE ASYLUM; NEUROLOGIST TO THE MULTNOMAH COUNTY HOSPITAL, ETC.

A LARGE proportion of the insane, not less than fifty per cent., should never have been born, and for this mistake physicians are to a certain extent responsible.

A young woman came under my care for acute mania. She was the affianced of a young man then in service in Cuba. She had suffered the usual distress present under such circumstances and her bravery had sustained her until her lover, after a severe illness, had returned to the United States. Upon receipt of a telegram that he was in the country and upon his way home in excellent health, she broke down completely and became so actively maniacal that three attendants were required to bring her on her journey of some hundreds of miles from a neighboring State for detention and treatment at Mindsease Retreat for mental cases connected with the Mt. Tabor Sanitarium. The family history disclosed the fact that the mother, before the girl's birth, had been insane and under restraint for some months; that at the time of her discharge from the asylum, then not quite recovered, the physician-in-charge had advised the husband and local doctor that the earlier pregnancy should occur, the better it would be for the patient. This advice proved good for the patient (although it would not ordinarily be so in one case in twenty) for, when pregnancy ensued a few weeks later, the mother entirely recovered her health which has since remained good.

There are others, however, involved in this momentous advice, how many, time and some generations of descendants being yet required to determine. The young woman referred to was its first victim. She made a good recovery, although the form of the malady in a few weeks became more and more of a melancholic type, which in time left her, and she was discharged from the institution. She was an educated woman, and she often spoke of the fact that, in view of her family history, she ought never to have been born. I talked to the father about her prospective marriage and, with his permission, gave my opinion to the young man, going over the whole subject in the presence of both these men so deeply interested in the grave problems surrounding the case. The patient was a sufferer from some ovarian disease which had made her somewhat of an invalid and I advised that the ovaries should be removed, not so much, however, on account of their diseased condition as to preclude the possibility of further propagation of defective offspring, marriage being, as is so often the case, insisted on both by the man and the woman to the prospective contract, in spite of the advice of the physician. I can see no serious objection to the marriage of a recovered case of insanity in a

[1]Read before the Wyoming State Medical Society, Oct. 10, 1900.

woman, if the dangers of the puerperium are eliminated and the prospects of progeny done away with through the removal of the ovaries, the prospective husband being informed of the condition of the woman and freely and in the presence of the family accepting the charge which this implies.

The sexual passion of the average woman, even with her ovaries, is of such trifling moment that ovariotomy need not on this account be largely considered. If the prospective husband is willing to enter the marriage bond with a recovered insane woman he should be even more willing to undertake the step if the danger of begetting offspring with such a taint has been entirely eliminated. Such a woman has thus a home, and I have known of several such instances where there seemed the highest degree of happiness to both parties. Recurrence under such circumstances is not at all likely; when it does take place, the effect is not very serious.

In the matter of marriage, the question of consanguinity is an important one. It would seem that Nature, heartless toward the individual, but careful of the race, as has been pointed out by one of our greatest poets, brings the hapless together in mating in order that the weaker strains may eventually become eliminated, and in no division of life is this fact more pronounced than in the tendencies of relatives to intermarry when neurotic or insane proclivities exist in the family. The disposition to intermarry in these cases has been said by many writers to come from the natural shyness of this class of individuals toward strangers and the consequent closer acquaintance with their relatives than with others. I believe, however, that it is more on account of the natural affinity of persons thus nervously situated.

We may lay it down as a rule to be invariably advocated that, when insanity is in a family, intermarriage should not be contracted. Unfortunately the physician's advice is seldom requested until after the engagement and then it is sometimes disregarded. It should not be difficult to break up such a match, because the defect is upon both sides and in either case a withdrawal may be pleaded on account of a condition of mental peril to the other on account of the weakness of the individual who is advocating the separation. It is quite difficult in other cases to break off a marriage into a family, no matter how notably insane. It is not easy for a young man to tell a young woman that on account of her family he must relinquish her; it is an ordeal which many young men will decline to undergo, preferring rather to chance future misery on untold generations, or more likely leaning upon that unreliable belief that no children will ensue as a result of such marriage, rather than inform the girl he loves most of any in the world that for any reason she is not good enough for him to marry.

When considering the tendency to insanity the time of the attack of the malady relative to the birth of the child is one of much moment in regard to the probabilities of the case. In the case of the daughter of a mother who late in life develops insanity, the father being of a vigorous, nervous stock, the daughter having been born early in the mother's life, there should not be given the same psychiatric value and objection to matrimony as though conditions were otherwise. In the case of a son under similar conditions a still more favorable opinion is possible. If the father had been the invalid and the mother healthy, a daughter's chances would be better than the son's, and *vice versa*. When there is a mental taint, either great or small, so far as the prospective offspring is concerned, if marriage is to be consented to at all, it should have our approval only when the other party to the contract comes of good, vigorous stock in which neither insanity, epilepsy or any of the grosser neuroses have been present.

When marriage has been effected the advice that no children shall be born is good, although it is much easier to give such advice than to enforce it. It is not often that a case comes under our knowledge, such as one recently known to me, in which a husband, whose mother died in an insane asylum from an illness resulting from traumatism, and who had himself two years before developed epilepsy after a meningeal inflammation, had duly considered the subject with his wife, and the sexual relation has been entirely suspended since the occurrence of the first epileptic seizure. The trouble is that people do not exactly understand the import of the mental and nervous symptoms, or, understanding them, do not feel like subjecting themselves to such rules of life as would be best under the circumstances. The best that we can do in most of these cases is to protest against large families, remembering that the ordeals of pregnancy, lactation and the care of rapidly-growing children are especially trying upon the nervous and mental powers of the neuropathic mother, and that a healthy woman in rapidly-supervening pregnancies is less able in her offspring to offset an evil mental tendency upon the part of her husband, as such pregnancies are repeated.

The husband, in either his own or his wife's defective condition, must be taught the absolute necessity for the sake of his children, if not for that of his wife, of extreme kindness and thoughtfulness toward the mother of the growing child during pregnancy and lactation. Everything of a distressing nature, which might through the mother produce an unfavorable result upon the child, must as far as possible be removed. Suitable food and exercise for the mother should be maintained during pregnancy, and it is an unfortunate thing when she must work too hard or be burdened with too many cares, family or otherwise, during this important period. A mother of a decidedly neurotic tendency should not nurse her child, both for her own sake and for the child's sake, and if she is of an irritable temperament, the child's early days should be passed in the hands of a carefully-selected nurse possessing equanimity of disposition, stability of character and the tact to govern children. It augurs well for such a child when it falls into such hands, and

I believe that if this were always so in these cases the percentage of insanity in this country would grow much less year by year, rather than show an increase as it does at present.

Sleep is the greatest foe which insanity has, as syphilis and heredity are its greatest friends. Multitudes of people sleep badly who are not insane and who will not become so, and in this country our most distressing patients are often found among those who are otherwise in fairly good health but who are troubled with insomnia. Because insomnia is not necessarily a precursor of insanity is no reason why we should not fully realize the pernicious possibilities along this line in individuals suffering therefrom. Against this symptom should be directed the very best efforts of the physician, because no one can tell until an explosion comes which is the serious and which the harmless case. It is so easy to give a hypnotic that we sometimes do so when we should not, and every effort should be made to relieve these cases by the use of a more suitable diet, proper outdoor exercise, the cold pack, baths, a vacation from work, and such changes in the ordinary affairs of life as may relieve those particular nerve-cells which are the victims of fatigue. We must remember our own responsibility touching the question of drug addiction, and be extremely careful that when a hypnotic is prescribed that the patient shall not have the opportunity of renewing the same without our orders.

During the past year no less than six patients in cases of drug addiction coming under our care have told me that the contraction of the habit was due to the physician in attendance. One of these was a patient for whom the drug was prescribed by his father, who was a physician. This habitué took the drug as a spray into the nose, as directed by rhinologists, before the cocaine habit was known. In this instance the habit had existed since long ago, when the first few grains had been administered. The physician in this case was entirely blameless, but I fear that in some other cases such was not entirely the fact, although I appreciate that the statements of these patients upon this subject are rarely reliable.

The food for the growing child of neurotic taint should be carefully selected and prepared. His food should be well cooked. His digestive apparatus, if defective, should be carefully studied and appropriately administered to. Clothing should be selected relative to the season of the year, but in the matter of both food and clothing his taste should not be pampered. He should sleep alone and have as much room as is convenient, with plenty of fresh air. His exercise should be of an outdoor, hardy character, even, if as is sometimes noted, there is a good deal of reluctance to outdoor life and to mixing with other children.

Masturbation in a boy should be guarded against. He should be warned at a tender age of the evils of this habit and a repetition of this warning should be made every year or so until he shall have reached the age of eighteen or twenty. In fact, this should be done in the case of all boys

A case of insanity under my care in a young man of twenty-five, in which masturbation was the undoubted cause, would not, in my own and the young man's opinion, have occurred, if the parent had given him timely warning. In this case, as in so many others, the carelessness of the boy's parents in not warning him and his own ignorance led up to the fateful sequence of this unfortunate habit.

The schooling of the child must be carefully planned. These children are, more often than otherwise, precocious, and the teachers and parents are proud to see their rapid mental development. Instead of being crowded, these little invalids, the irritability of whose nerve-cells rather than their special energy being the cause of their apparent brightness, should often be taken out of school, and, in any event, a brake should be put upon their ambition and their work. They had better be taught to strive to become like the ordinary child, rather than to be the exception.

Another class in the mental defectives embraces the dull child, who is often abused because of his stupidity until life becomes a burden to him. Although this represents a phase of mental character upon the other extreme, for both of these classes a special course should be selected at school, and those branches which are most difficult for them should be reduced to a minimum or entirely eliminated. It is much better that these individuals should reach middle life in good mental form, although not specially noted as scholars, than that they should carry off honors at school and college, because they have taken the full course and have on such account reached middle life in an indifferent state of mental health, if no more serious condition than this has supervened.

In all things the child should have his life shaped so that he is to be a man in the middle of the marching column. He should not be a leader and bear the necessary responsibilities consequent thereto. Neither should he be subject to the torments which afflict one who is harassed by being the last man, "the under dog." In the latter class are developed the dangerous anarchistic insane, many of whom are not confined but go about the world stirring up trouble. Moderation, therefore, should be enjoined and he should not be encouraged to believe that he is an individual above the ordinary, for the ego is usually unduly developed in nearly all of these cases.

As a business-man he should enjoy an out-of-door life as much as possible. His habits should be regular and he should be temperate in all things. We are all able to do better work, we are told, in eleven months than in twelve during any year, which I believe is quite true, but I know it is especially so with a man who has a weak place in his mental make-up.

The surgical defects of our patients who have possibilities for mental trouble before them should have the careful attention of our surgeons. Many cases become markedly improved after having been under the surgeon's care. Troubles which are a source of much worry, such as urethral stricture in men, hemorrhoids in both sexes and pelvic

disorders in women, merit attention, although in some instances surgical work has been carried to an extreme in this regard. I saw at Salt Lake this week a case in which a woman who had been insane had been subjected to the loss of her ovaries for insanity. Although the great nervous shock of a surgical operation of this character may sometimes shake the insane individual out of a state of lethargy and augment recovery, that result is so rare that the removal of healthy ovaries for insanity is, as an act of neurotherapy, an obsolete procedure. Nevertheless I always feel, as in the case mentioned, that when the gynecologist removes the ovaries, healthy or diseased, from an insane woman, unless the patient should die, he is doing a possible service to the race, although the mental recovery in such cases may not be accelerated.

Unlucky is the day in which a mental defective contracts syphilis and more so when the treatment therefor is insufficient. The terminal dementias and mental pareses are largely syphilitic in origin and in many of these cases treatment has not been thoroughly administered, largely because the mental state of these individuals makes them bad patients upon whom to enforce protracted treatment. In the young with congenital symptoms of this disease, where they is a tendency to insanity, it is inexcusable for the physician to fail to administer a full course of specific treatment.

All epilepsies need our closest attention: especially true is this regarding the *petit mal* forms. When one of our patients complains of sudden, dizzy spells and sometimes of moments of loss of consciousness, although she may not fall nor make an outward sign of this condition noticeable to others, it behooves us to take prompt measures at this time of probable cure for the relief of a condition which will likely lead on to *grand mal* attacks.

Hysteria and neurasthenia and kindred states must not be overlooked, but require as careful care as though a more acute illness was present. The strain upon the nervous system in these conditions is always great, and in occasional cases insanity does follow. Alcoholism or the gambling habit, whether with cards, in stock or otherwise, is a business or a sport for others than those of whom I am speaking. The nervous strain is too severe and both in success and in losses have I seen mental illness occur. The easiest prey seems to be he who has gone through many trying ordeals, including want and suffering, and who suddenly finds himself rich. Two cases like this have come to me from Alaska in men who had suffered from long misery, under which they had stood up bravely and without much apparent ill effect, to break down when Fortune smiled upon them. Both of these, however, were defectives and one had been a subject of syphilis fifteen years before.

THE TONOMETER AND ITS VALUE IN DETERMINING ARTERIAL TENSION.[1]

By HENRY L. K. SHAW, M.D.,
OF ALBANY, N. Y.;
INSTRUCTOR IN PEDIATRICS IN THE ALBANY MEDICAL COLLEGE.

THE first experimental attempt to study the blood-pressure was made in 1727 by Stephen Hales[1], an English clergyman. He exposed a superficial artery in a horse and inserted a canula to which a straight glass rod was attached so that the height of the blood-stream could be observed. The hemometer of Magendie[2] appeared later, improving on Hales' apparatus in substituting for the straight tube a U-shaped glass tube filled with mercury. Nothing was done to determine the arterial pressure in man until 1856 when Faivre[3] inserted Magendie's hemometer in arteries exposed during operations.

The late Professor Albert[4] was interested in this subject and published the results of a long series of experiments, similar to those of Faivre, in 1883. Stricker[5] in 1866 proved that the capillaries are contractile; that changes in the size of their lumen can be produced by electrical irritation, and that this is associated with raising or lowering the arterial pressure. Marey[6] was the first to devise an instrument which could be used clinically, not surgically, to determine the arterial pressure. This instrument was not perfected until 1878. A number of appliances have since been devised, but most of them were too complicated for every-day use and suitable only for the physiological laboratory. The best known are those of Potain[7], Von Basch[8], Frey[9], Mosso[10], Hürthle[11], Oliver[12], Hill and Barnard[13] and Riva Rocci[14]. Some were most ingenious, but few proved practical. The sphygmomanometer of Von Basch had the greatest employment on account of its simplicity, and much valuable information regarding the blood-pressure was obtained through its use. Its worth, however, is relative, not absolute, and on account of its unreliability and large range of error it is not in large demand. Moreover, much skill is required to obtain even approximate results.

[1] Read at the annual meeting of the New York State Medical Society, Albany, January 28, 29, 30, 1901.

The simpler the mechanism and application of such an instrument the less is the personal error and the more valuable are the results. The tonometer is the most recent instrument of this sort and I desire to bring it to your attention. It was invented by Dr. Gustav Gaertner[15], Professor of Experimental Pathology at the Vienna University. He first exhibited the tonometer before the Vienna Gesellschaft der Aerzte in June, 1899. It met with instant approval and was at once employed in the wards of Nothnagel and Neusser at the Allgemeines Krankenhaus. Since then it has grown in favor throughout Austria and Germany. Descriptions of the tonometer with favorable comments have been made by Tschlenoff[16], Weiss[17], Schüle[18], Doering[19], Doleschal[20] and others. Doleschal made several hundred tests with the tonometer and sphygmomanometer for purposes of comparison and concluded that the tonometer was more exact, easier to apply and simpler to manage.

The tonometer consists of a pneumatic ring, mercury manometer, rubber ball and rubber tubing. The ring is made of metal and large enough to easily slip over and cover one of the phalanges. There is a hole in one side where the rubber tube is attached. The inside of the ring is covered with a thin rubber membrane and is air-tight, the only place that air can enter or escape being through the opening in the side. The manometer is simply a glass tube with a bulb filled with quicksilver. A scale is attached which registers up to 260 mm. The tubing is T-shaped with the ring, manometer and rubber ball attached on the free ends. These parts are separable but by the use of leather washers the joints are made air-tight. Pressure on the ball forces the air into the mercury bulb and pneumatic ring, raising the mercury in the one and distending the membrane in the other. To slowly regulate the pressure on the ball there is a small wooden press with a thumb-screw in which the ball is placed. Professor Gaertner has designed a small aneroid manometer which registers the same as the mercury scale and which can be carried in the pocket.

The technic is simple. The pneumatic ring is slipped over the second phalanx of one of the fingers and the blood removed from the finger-tip by rolling a small rubber band down to the joint. The rubber ball is then compressed until the pressure exerted upon the digital arteries by the ring is greater than that of the blood in the arteries. The rubber band is withdrawn and the finger-tip should remain anemic. The pressure on the ball is slowly and evenly diminished until the finger-tip becomes intensely red. The height of the mercury in the tube is then recorded.

All the earlier instruments were constructed so as to find when the pulsation in the vessel disappeared. Professor Gaertner reversed this and the tonometer records the pressure when the pulsation reappears. The finger is admirably adapted for this purpose. The two digital arteries provide the blood-supply and these are close to the surface and near the bone, and so can be completely compressed by the pneumatic ring. When the rubber band is removed and the finger remains anemic it shows that the ring is exerting a greater pressure than that in the arterial system. The pressure in the ring is gradually reduced, and the instant the pressure in the ring is equal to or a little less than the pressure in the arterial system the blood will flow through the arteries and the finger-tip will become hyperemic. The same instant a marked pulsation is felt by the patient. The mercury scale records exactly the amount of pressure exerted upon the finger, so that when the finger-tip becomes red the amount registered on the scale is approximately the amount of blood-pressure in the digital arteries.

The tonometer is not above criticism, nor is it perfect, but it is by far the simplest and most satisfactory instrument for the estimation of the blood-pressure yet devised. It must be absolutely air-tight and the rubber ring and tubing must be frequently renewed, as the rubber rapidly deteriorates when not in use, especially in summer.

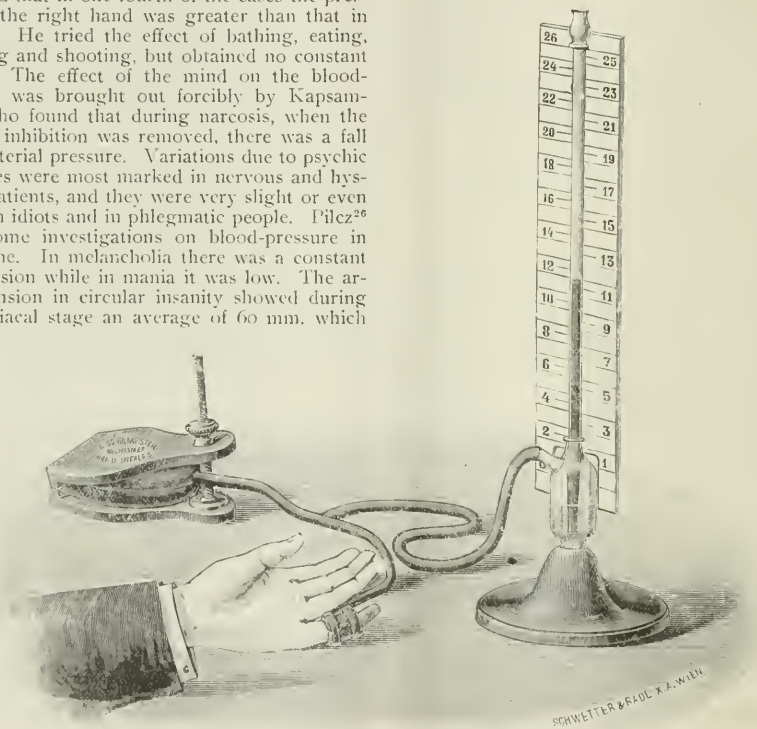
The difficulty in deciding about the tension of a pulse is well known, for the sense of touch is not infallible. As long as digital examinations are made to study the blood-pressure no exact deductions can be made. Oliver[21] says that our knowledge of arterial pressure is limited because our methods and means of observation have been faulty.

The blood-pressure is dependent on three factors: (1) The amount of cardiac power; (2) the amount of peripheral resistance; (3) the amount of blood in the vessels. The pressure is usually determined by the force the finger has to exert in order to stop the flow of blood in the radial artery. Physiologically there are three pressures; the maximal, minimal and middle. The maximal is the systolic, the minimal the diastolic, and the middle pressure is the average of the two. In general when we speak of the arterial pressure we refer to the middle pressure. To recognize these degrees of tension is an art and requires much skill and experience. A. Fraenkel[22] claimed that the tonometer records only the maximal pressure, a great fault of most of the previous instruments. To settle this point Gaertner[23] recently made some original and interesting experiments. He procured some dogs with white tails. The tails were shaved and rendered anemic by means of a rubber band, and the pneumatic ring applied. When the pressure in the ring was reduced to the proper point the section of the tail became red. The direct pressure was obtained by inserting a canula in the carotid or crural artery and at the same time the pressure in the vessels of the tail was determined by the tonometer. Different sets of observers attended to the two readings. The maximal and minimal pressures were obtained by the direct method and the average of the two gave the equivalent of the middle pressure. In every test the tonometer recorded either the exact middle pressure or a few millimeters above or below. This proved the absolute worth of the tonometer.

The conditions where an exact knowledge of the blood-pressure is important and even diagnostic are numerous.

A number of articles have appeared in the foreign medical journals this past year on work done with the tonometer. An exhaustive study of the arterial pressure in healthy adults was made by Jellinek[24]. He found that the normal pressure in 532 soldiers averaged between 100 and 160 mm., and that in one-fourth of the cases the pressure in the right hand was greater than that in the left. He tried the effect of bathing, eating, marching and shooting, but obtained no constant results. The effect of the mind on the blood-pressure was brought out forcibly by Kapsammer[25] who found that during narcosis, when the cerebral inhibition was removed, there was a fall in the arterial pressure. Variations due to psychic influences were most marked in nervous and hysterical patients, and they were very slight or even absent in idiots and in phlegmatic people. Pilcz[26] made some investigations on blood-pressure in the insane. In melancholia there was a constant high tension while in mania it was low. The arterial tension in circular insanity showed during the maniacal stage an average of 60 mm. which rose to 160 mm. in the period of melancholia. In the early stages of general paralysis the tension was normal, but it gradually sank as the disease progressed so that the tonometer would register between 50 and 80 mm. in the terminal stage.

Heim[27] found there was a high tension in neurasthenia and hysterical children and claims this constitutes an important diagnostic point. Neisser[28] emphasizes the importance of a correct estimation of the blood-pressure at the bedside both for prognosis and treatment. He has also found it of value in the prognosis of acute infectious diseases. One of the assistants in Nothnagel's clinic, Czyhlarz[29], ascertained the arterial tension before and after the administration of digitalis to cases with uncompensated heart-lesions and to healthy individuals. He reported that digitalis in small doses had no effect on the arterial tension nor on the amount of urine excreted in persons whose circulatory systems were normal. The same dose, however, in patients with heart-disease caused an increase both in the arterial tension and in the amount of urine passed. Lepsius and Schott[30] of Nauheim found by means of the tonometer that the carbon-dioxide baths brought about an increase of 10 to 20 mm. in the arterial tension of patients suffering from heart-disease. A. Fraenkel[31] described a case of albuminuria in which a digital examination of the pulse showed no increase in tension and where a marked increase was revealed by the tonometer. Grebner and Grünbaum[32] tested the effect of muscular work on the blood-pressure and found that there was an increase during the work which depended on the amount of work and the training of the individual. When the work ceased there was a fall in the pressure. They also showed that posture, time of day and respiration influenced the arterial tension. Wagner[33] claims that there is a fall in the blood-pressure during sleep. Kapsammer[34], who was one of Albert's assistants, made a number of experiments to discover the lowest fall, compatible with life, in the blood-pressure



during operations. In several of his cases where the tonometer registered below 60 mm. there was a normal pulse frequence and respiration, but they ended fatally from twelve hours to six days after the operation. He believes that 60 mm. is the lowest limit compatible with life and that the fall in pressure has more prognostic value than the respiration and the pulse. Schröder[35] studied the blood-pressure after gynecological operations and plotted out curves from the variations which he claims are as constant after certain operations as are temperature curves in certain diseases.

THE PRESENT STATUS OF THE SUBARACHNOIDEAN INJECTION OF COCAINE FOR ANESTHESIA (CORNING-BIER METHOD).[1]

BY JOHN S. MILLER, A.M., M.D.,

OF DENVER, COL.;

EX-SURGEON TO ST. JOSEPH'S HOSPITAL, PHILADELPHIA, PA.; DEMONSTRATOR OF ANATOMY IN THE GROSS MEDICAL COLLEGE, DENVER, COLORADO.

AT this time there is probably no subject in medical literature which is receiving more attention than the subject mentioned in the above title. This procedure has been variously named by different authors. It is not my desire to criticise these titles. Some are inaccurate and others misleading. The following are sample titles taken at random from current literature: "Medullary injection of cocaine for analgesia," "medullary analgesia," "medullary narcosis," "subdural infiltration," "spinal anesthesia," "cocaine anesthesia of the spinal cord."

To the author it would seem that "subarachnoidean injection of cocaine for anesthesia" would be rather more descriptive and more nearly anatomically correct. While this method enables us to produce anesthesia over about four-fifths of the body, from the toes to the level of the clavicles, nevertheless, it is only a contribution to local anesthesia by cocaine in contradistinction to general anesthesia by the inhalation method. Not unlike many other discoveries and advances in medicine it must pass through the ordeal of a period of probation, divided into three stages, *viz.*, enthusiasm, moderation, and finally therapeutical approbation. A superficial perusal of the current literature on subarachnoidean injection convinces one that the results of the application of this method are not always uniform or desirable. Thus an element of doubt presents itself as to whether all the operators have been exact in their technic or discreet in the selection of cases.

The spinal canal contains a structure of a highly-organized and sensitive character, encroachment upon its domain being in many instances more serious than upon that of the brain, owing to its anatomical inaccessibility in after-treatment, as, for instance, in streptococcus or other infection. It is true that the area directly involved in this procedure is no longer traversed by the spinal cord, but by a leash of nerves called the cauda equina. It is at this point that the cocaine solution, although diluted by the cephalorachidean fluid, has its strongest effect, thence by diffusion it anesthetizes the spinal roots higher up in the canal. The membranes and spaces are continuous with those of the cord above. The cocaine solution is rapidly disseminated upward, and, when injected between the fourth and fifth lumbar vertebræ, the analgesia ordinarily extends from the toes to the costal arch.

Fowler reports two cases of puncture between the second and third lumbar vertebræ in one of which the analgesia extended to the clavicular level; in the other, to the supra-orbital region. These peculiar deviations do not seem to depend upon the strength of the solution, nor on the amount of cerebrospinal fluid withdrawn. This phenomenon has not as yet been satisfactorily explained.

Is is safe to predict that in the near future some venturesome surgeons will try to outpoint their colleagues by injecting an intervertebral space higher with each operation and will thus gradually invade the ground now considered physiologically forbidden until they meet with disaster. It is claimed that idiosyncrasy to cocaine intoxication enacts an important rôle in this form of anesthesia. While it is well understood that cocaine behaves very erratically in many cases when administered either hypodermatically or by absorption, it would seem that the undesirable side-effects of subarachnoidean cocainization are produced by the same *modus operandi*.

[1] Read before Arapahoe County (Col.) Medical Society, Nov. 20, 1900.

namely, diffusion. In quite a number of cases reported the caloric and respiratory centers were involved to a most alarming degree. Probably the deaths reported were due to this cause. An anatomical study of the spinal canal teaches us that the blood-vessels and lymphatics are chiefly extradural, and that the subarachnoid membrane and pia mater can absorb but little of the drug. As the author reasons, the action is a local one upon the posterior nerve-roots, also, that when higher centers are involved it is by diffusion through the spinal fluid, and not through absorption by the spinal cord. The anesthesia of the nerve-roots from their point of entrance into the spinal canal to the postero-lateral groove of the cord, inhibits the transmission of sensation.

That this theory is plausible can be demonstrated by injecting solutions of cocaine, eucaine, or nirvanine into the immediate vicinity of a peripheral nerve-trunk and thus anesthetizing the entire area of its distribution. The idiosyncrasy to cocaine intoxication must not be overlooked, particularly when the solution comes in contact with a vital center. Therefore, it is presumable that the higher the injection is made, the greater the degree of danger. It would be quite an interesting experiment to study the diffusibility of a cocaine solution in the lumbar subarachnoid space of a dog. The animal should be immobilized in a box with his legs protruding from the bottom. The dog resting as in the standing position. He is next etherized (dogs do not bear chloroform well). The cocaine solution should be impregnated with some chemical which should not increase its specific gravity or diffusability in the spinal fluid. The hide is split up the dorsum and rapidly turned aside and a few drops of the fluid drawn off at different intervertebral points. A number of test-tubes should be at hand, containing a chemical solution which would show a reaction when the changed spinal fluid is added. A salt solution injected would give a milky reaction with a solution of nitrate of silver; or, chloride of iron added to the injection would give a black or inky reaction when added to a solution of tannic acid.

Probably, the best method would be to evaporate the fluid obtained and thus recover the crystals of cocaine. This of course would be quite tedious. The animal should be weighed and the dosage should be in proportion. Physiologists have a rule governing these proportions. Three points might possibly be demonstrated: (1) The rate of diffusion; (2) the strength of the solution at the most remote point; (3) the recognition of the drug in the ventricles of the brain. This is only thrown out as a suggestion which may be improved upon.

The enthusiasm of the surgeon must be tempered by the conscientious observance of the most minute details. To be misled by the *furor* is both reprehensible and sad. Cases should be carefully selected, and *this variety of anesthesia should be used only when ether and chloroform are contra-indicted.* As afore-mentioned, cocaine is at times very perverse in its physiologic effects; this also holds true when it is introduced into the spinal canal. Two cases were recently reported in which a minimum dose of fifteen minims of a one-half-of-one-per-cent. solution injected into a robust man was followed by most alarming symptoms. Six hours were spent in reviving this man, before he was considered out of danger. In another case, a feeble woman, twenty minims of a fresh four-per-cent. solution were injected. The analgesia merely reached the thighs and lasted only thirty minutes. The operation, one for hemorrhoids was finished under ether anesthesia. Subarachnoidean anesthesia has advantages which time and experience alone can determine. Its advantages at this writing do not appear to outweigh its disadvantages. Improved technic and further research will undoubtedly give it a certain sphere of usefulness in the armamentarium of the surgeon.

A decided advantage over general anesthesia is that the respiratory, cardiac and renal organs are not so seriously disturbed as by the inhalation method. Pneumonia is quite common in the feeble or aged after prolonged ether narcosis. All renal trobles are aggravated and prompt *exit lethalis* is often induced. Such cases are never reported as deaths from ether narcosis. The same is true of chloroform, when administered in obscure cardiac or brain cases.

The vomiting and nausea after ether, and sometimes after chloroform, are serious factors in inducing secondary hemorrhage in abdominal sections, brain or neck operations. We admit that vomiting and other symptoms are often present in the subarachnoidean method, but these can be overcome in a great measure by careful preliminary preparation of the patient and by an intelligent technic. Still another advantage is that of the ability of the patient to confer with the surgeon during the operation in case a modification of the original plan must be made and the patient's consent is necessary. As for instance, a tumor of the breast, arm or leg may be diagnosed as being of a benign character; during the operation the discovery is made that the neoplasm is sarcomatous and consent for amputation may be required. The disadvantages are severe, such as almost uncontrollable headache, lasting sometimes a week, nausea, vomiting, vertigo, cyanosis, elevated temperature, weakness and relaxation of the sphincters sometimes lasting several days. During the operation the patient may become apprehensive and restless, and the psychological disturbance may cause decided interference. Fowler reports a case in which he had to administer general anesthesia to finish the operation for this reason.

On the whole, the reports of American operators are more favorable than those of our European colleagues. Can it be that we are more careful than they in technic? Fifteen minims of a two-per-cent. solution of eucaine were used very satisfactorily by Keen. This drug can be boiled without destroying its physiological prop-

erties. Other observers are not so well pleased with this drug. Fowler has tried antipyrin on a stoical, illiterate Italian woman, but he cannot say that it was satisfactory. I have not learned as yet that nirvanine has been used in this way. It is ten times less toxic than cocaine and is in itself an antiseptic. Its analgesic effects are as strong as that of cocaine.

Various reasons are assigned for the many untoward complications and failures, such as stale solutions, non-sterile solutions, excessive dosage, insufficient dosage, failure to deposit the solution into the subarachnoid space, trauma by the needle of the nerves in the cauda equina, the liberation of too much cephalorachidean fluid, the liberation of none or not enough, the use of the needle if it is too large and permits the escape of cocaine solution along its sides, the use of steel needles which are apt to break, the too early removal of the needle and escape of the solution into the erector spinæ muscles.

The matter of preparing the solution has not been settled. Corning is satisfied with boiling his solution for five minutes in a test-tube. Tuffier prepares his solution in the laboratory. The cocaine is first dissolved in sterile or distilled water, then sealed in glass bulbs and subjected for one hour on two successive days to a temperature of 175° F. Goldan boils filtered water ten minutes; he then pours off the excess, leaving one dram to which he adds the cocaine and keeps the solution just below the boiling point for two minutes. This insures a sterile solution. He has met with success in 25 cases, and advises making a fresh solution for every case and not keeping it from day to day. J. Bion Bogart boils the solution two minutes and has had excellent results in a large number of cases.

Probably the sterilized cocaine solution put up by a Chicago house is the most convenient and reliable form. It is generally understood that cocaine loses its efficacy when boiled. Goldan (Medical News, Nov. 19, 1900) says: "After considerable experience and careful study I have arrived at the following conclusions: That the intraspinal cocainization would be superior to general anesthesia, as administered in many cases, there is no doubt. That it is superior, either in safety or advantages, to our three anesthetics properly selected and skilfully administered, I, for one, do not believe."

Tuffier says that cardiac disease is not a contra-indication. M. Racoviceneau-Petesei, after an experience of 125 cases, does not believe that this method will replace ether or chloroform anesthesia.

Marx has had an experience of forty cases in obstetric practice and speaks of the method in the most flattering terms. Dr. W. Mitchell of this city prepares the solution after his own method, which is both scientific and reliable. It is strictly aseptic.

In conclusion, I hope it may not be considered bold or presumptious on my part to suggest that there is a medico-legal element in these experiments. To avoid the possibility of a suit for damages in case of accident or untoward results, it would be advisable to secure absolute consent of the patient and family, in writing or in the presence of witnesses, after explaining to them the merits and disadvantages of this procedure which carries with it no small element of risk.

CLINICAL MEMORANDUM.

A CASE OF PERONEAL NERVE-PALSY FROM MUSCULAR EFFORT.

BY CHARLES J. ALDRICH, M.D.,
OF CLEVELAND;
LECTURER ON CLINICAL NEUROLOGY AND ANATOMY OF THE NERVOUS SYSTEM IN THE CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS; VISITING PHYSICIAN AND NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CLEVELAND CITY HOSPITAL.

The following case of traumatic neuritis of the peroneal nerve, undoubtedly due to muscular effort, is believed by the writer to be unique and worthy of detailed report.

E. L. M., male, white, age twenty-two years, United States born, commercial traveler; previously healthy; family history good. In March, 1899, while alighting from a slowly-moving tram he stepped upon an inclined plane, slipped and fell. To save himself when falling he sat down, sharply flexing the left ankle and knee. At once he experienced severe pain from the knee downward in the leg, and when he attempted to stand the hamstring muscles drew the leg upward and prevented him from extending it. To use his own words, "it cramped."

He was taken in an ambulance to a hospital where it was found that, while he had suffered no fracture, the contraction of the hamstring muscles was so great as to prevent extension. Pain was very severe on the top and side of the foot and ankle. The "bottom of my foot," as he expressed it, "was all right." Power was at once lost in the extensors of the foot and ankle. Sensation to touch was also lost in the areas of pain. Hot-water bags applied to the limb blistered all of the areas over which he was anesthetic. The scars of these blisters are yet plainly seen. The blistered surface was extremely slow to heal. There was some swelling of the foot and some in the fibular region of the leg, most marked on the dorsum; considerable ecchymosis on the outer aspect of the leg from the tibiofibular articulation down to the ankle, particularly marked, however, near the attachment of the muscles on that side.

He was in the hospital four weeks, during which time the spasm of the hamstrings relaxed allowing extension of the leg. He slowly recovered the power to stand and walk with the aid of a cane.

Examination Nine Months After Injury.—He seems to be a healthy person in every way. Plan-

tar reflexes normal. The tendo-Achillis jerk on the left side is distinctly increased. On this side he has a typical drop-foot, total inability to flex the foot on the leg and extend the toes because of the complete paralysis and atrophy of the tibialis anticus, peronei, extensor longus digitorum pedis and extensor propius hallucis. The left leg measures one and one-half inches less than its fellow.

The atrophy and areas of anesthesia are very nicely shown in these photographs which Dr. John Nuss kindly made for me. The area of anesthesia accurately corresponds to the cutaneous distribution of the musculocutaneous, anterior tibial and other cutaneous branches of the peroneal nerve. Reaction of degeneration was demonstrated in the peroneus longus and tibialis anticus. The opinion of several very careful

Fig. 1.

The flat surface of the left leg in the photograph is in marked contrast with the rounded fulness of its fellow. It also shows the dark lines along and between the toes separating the areas between the anesthesia in the distribution of the anterior tibial and the musculo-cutaneous from the normal areas supplied by the internal and external plantar nerves.

surgeons is that he did not suffer either a fracture or a dislocation.

If one will recall the anatomy of the parts, he will remember that just behind the knee, the external popliteal or peroneal nerve passes obliquely outward and downward on the inside of the tendon of the biceps; passes between the tendon of the biceps and head of the gastrocnemius muscle, winds around the head of the fibula, pierces the peroneus longus near its origin and divides beneath the latter muscle into the anterior tibial and musculocutaneous nerves.

It seems only reasonable to suppose that the sudden and powerful muscular action intended to prevent his falling resulted in a severe contusion of the nerve by the contraction of the peroneus longus, or, which is still more likely, the nerve was torn along with the muscle, the evidence of which latter injury appeared later in the extensive ecchymosis which took place, and which was most marked about the attachment of the peronei.

Careful examination of the literature of injury and traumatic neuritis of the peroneal nerve reveals no case which possesses like origin, *i.e.*, muscular effort.

Fractures of the head of the tibia and fibula or dislocation of the latter are not infrequently responsible for quite a number of injuries of the peroneal nerve and its branches, as is attested by Perrin[1], Duplay[2], Callender[3], Terrier[4], Bowlby[5], Verneuil[6], Berger[7], Smith[8], Szuman[9] and Watt[10]. Hogarth[11] has reported two cases due to direct blows received while playing football. In neither of his cases was there fracture or dislocation. It is not impossible that in one of his cases the injury was laceration of the nerve due to muscular effort, since he clearly states that there was separation of the muscular tissue.

Fig. 2.

This side view shows the area of complete anesthesia on the leg which has sensibly narrowed from a point but little below the head of the fibula; showing that the injury took place above the origin of the lateral cutaneous branch of the peroneal nerve.

In conclusion I can but echo the observation of Hogarth, that when we consider the exposed position of the peroneal nerve it is remarkable that it so infrequently suffers injury.

MEDICAL PROGRESS.

Tuberculosis in Prisons.—While so many are interesting themselves and others in the State care for consumptives, it is strange that so little attention has been paid to State institutions already existing, such as prisons and reformatories, where no pretense is made to control the spread of this disease. S. A. Knopf (*Med. Rec.*, March 2, 1901) shows what an important factor in the death-rate tuberculosis has become even in such institutions as the Sing Sing Penitentiary and the Elmira Reformatory. In spite of this fact, even ordinary precautions are seldom taken to isolate the disease. The prisoners mingle indiscriminately, no spit-cups or even spittoons are provided, as a rule, and a well person is frequently compelled to live in a small cell with a tuberculous prisoner. The sources of possible infection in such an institution are, of course, innumerable and it is astonishing that health boards have not taken more active steps toward preventing the dissemination of this scourge. To regard the disease as a blessing among the prisoners is not only most unjust to the unfortunates but also to the public, for many of the former will later be freed and prove a nuisance to their associates or perhaps become burdens to society on account of their invalidism.

Roentgen-Ray Treatment of Tuberculosis.—Following upon the success which has attended the use of the X-ray in cases of lupus, numerous efforts have been made to destroy the tubercle bacilli in other parts of the body, especially in the lung. J. Rudis-Jicinsky (*N. Y. Med. Jour.*, March 2, 1901) prepared cultures of several species of bacteria, including diphtheria, tubercle bacilli, anthrax, etc., and found that the effect which the X-ray had depended largely upon the reaction of the culture medium. Those grown upon an alkaline medium seemed to thrive under the stimulus of the rays, but those in acid media were destroyed. Rabbits, inoculated with tubercle bacilli and whose secretions were rendered alkaline soon died of tuberculosis. Others inoculated from the acid media, having been in the first stage of tuberculosis, were then exposed to the intense irradiation daily and were in good condition at the end of two years. The same treatment has been used by the author in many early cases of pulmonary tuberculosis and in nearly every case marked improvement has taken place. Other methods of treatment have been combined with this, so that it is impossible to conclude that the cures were due solely to the X-ray exposures.

Formaldehyde in Suppurative Otitis Media.—In those cases of otorrhea which are susceptible of cure by syringing with an antiseptic solution, H. O. Reik (*Maryland Med. Jour.*, January, 1901) believes that formaldehyde will accomplish the good result with more certainty and in a much shorter time than any other antiseptic now employed. In thirty-one chronic otorrheas the greatest length of time required to bring about a cessation of the discharge by the use of formaldehyde was twenty-eight days, while the average time was nine days. Only four cases were not improved. In sixteen acute cases the average time required was five and one-half days. The evident advantages which formaldehyde has over boracic acid and bichloride are : (*a*) Its bactericidal power compares favorably with that of bichloride or any other agent; (*b*) it can be entrusted to any patient with safety; (*c*) it has great rapidity of action and also a stimulating effect upon the local tissues. As to the manner of using formaldehyde, Reik has found it most satisfactory to use one dram of the commercial solution of formaldehyde (40 per cent.) in one pint of boiled water, and to direct that the ear be syringed twice daily, using at least a pint of the mixture at each sitting. This is equivalent to a 1-300 solution of the formaldehyde gas. Stinging sensations usually follow its use, but the amount of discomfort is slight, and lasts only a few moments. In sensitive ears a weaker solution can be used.

Hemorrhage from Peritonsillar Abscess.—Severe hemorrhage from quinsy is rather rare, but, on account of its peculiarity in usually being secondary to ulceration, the following case of W. P. Chappell (*N. Y. Med. Jour.*, March 2, 1901) is of interest. This patient presented an ordinary case of quinsy, the abscess pointing in the middle of the posterior pillar. A small longitudinal incision was made and the pus evacuated. Four days later, the patient had a severe pain in the throat and then lost about six ounces of blood. He had two similar hemorrhages during the next five days. A large incision was then made through the anterior pillar to the cavity, which was packed with iodoform gauze. There have been ten cases reported previously and all seem to indicate that the hemorrhage is due to the ulceration of the ascending pharyngeal or the internal carotid artery. The treatment should, therefore, be to incise the abscess early, maintain free drainage to avoid ulceration and, if the hemorrhage occurs, to adopt the method described or ligate the carotid artery.

Ureine.—At the International Medical Congress, W. A. Moor read an account of the Discovery of Ureine, the Principal Organic Constituent of Urine and the True Cause of Uremia. So satisfactory was his explanation of the methods of his work that A. F. Chace and W. J. Gies (*Med. Rec.*, March 2, 1901) have endeavored to learn the truth of his statements, and have become thoroughly convinced that his conclusions were not founded upon scientific experimentation. They have found that it is not a chemical individual, but a mixture

containing several of the organic substances and a considerable proportion of inorganic salts ordinarily found in normal urine and that its toxicity can be referred to some of these normal constituents. Dr. Moor's method of preparing urine fails to eliminate potassium salts and many normal basic alkaloidal bodies which are known to possess very toxic properties.

Plague Antitoxin.—Immunity to a certain disease may be artificially conferred either by injecting into a person serum taken from a patient or an animal that has lately acquired the disease; or the person may be directly inoculated with the attenuated germs of the malady or their toxins, and thus develop a mild form of the disease, not fatal, but sufficient to stimulate the manufacture of the immunizing substance. C. B. Stewart (*Indian Med. Rec.*, Jan. 16, 1901) refers to the work which has been done to obtain a successful antitoxin for the plague. Yersin's serum is based upon the same principle as the diphtheria antitoxin, the horse being the animal in which the antitoxin is developed. This serum is curative and also used as a prophylactic agent, but the immunity conferred is very short—only about fifteen days. Haffkine has lately developed a method by which the person may be given the plague in a mild form and thus obtain an immunity of a much longer duration. A sterilized culture of the plague microbe in broth is used as a vaccine. The microbe is obtained fresh from a case of plague and incubated in flasks of broth at 70° to 80° F. After being tested and found pure the culture is sterilized by heating to 65° C. for one hour and a small quantity of carbolic acid is added. These dead microbes, with the broth which contains considerable toxic properties, are injected into the person in gradually increasing doses, until the antitoxin has been sufficiently developed to immunize the individual.

Tetanus Antitoxin.—In determining the value of antitoxin in tetanus, W. Wilms (*Münch. med. Woch.*, Feb. 5, 1901) says that the following two facts must not be lost sight of: (1) That the treatment is not begun later than thirty hours after the onset of the first symptoms; (2) that the amount used at once is not less than 100 units. In view of the fact that as many as 60 per cent. of cures have been recorded, the author investigated the records of the Leipzig hospitals to discover that the antitoxin proved a failure in nearly all cases. This leads him to conclude that in all previous statistics many chronic cases of tetanus have been included and that in these the results have been much more satisfactory. The conclusions of Behring to the effect that the mortality could be reduced by 15-20 per cent. could thus not be verified.

Plasmodium Malariæ.—Our present knowledge of the causative agents of malaria is summed up in an interesting article by B. Galli-Valerio (*Therap. Monatshft.*, Feb., 1900). After an account of the history of the plasmodia and the various forms found in the lower animals, he describes the human parasites as follows: The cause of tertian fever may occupy the entire red blood-cell, has rapid, ameboid movements and fine granulations and completes its cycle within forty-eight hours, forming twelve to twenty spores. That of quartan fever may also replace the entire red cell, but has slower movement and coarser pigment and a cycle of seventy-two hours' duration with a division into six to fourteen spores. The third form, the parasite of pernicious fever, occupies only one-fourth to one-fifth of the cell, is capable of very rapid movement, is ring-shaped when at rest, shows very fine, hardly-perceptible pigment and completes its cycle within forty-eight hours, chiefly in the internal organs. The inoculation of any one of these three forms will always cause a fever of the corresponding type. The fever coincides with the endoglobular phase in the development and may be due to a toxin, though this has not as yet been isolated. The development of the parasite outside the human body has been studied in the stomach and intestines of the mosquito. Twelve hours after this has taken up infected blood, the spermoid which has penetrated the female yields fertilized bodies which migrate between the epithelial cells after forty hours. Spindle-shaped forms develop in these, which, after bursting the limiting capsule, fall into the body-cavity and then, by means of the circulation, reach the salivary glands where they are stored up in large numbers. The most important transmitters of malaria are *Anopheles claviger, bifurcatus* and *superpictus*. Though a specific for the treatment of malaria exists, the tendency of the present day is to destroy these insects by the cultivation of certain fish and by the use of petroleum and aniline colors. But much can be done by protecting the windows of houses in infected regions with fine wire-netting.

Chloretone.—A. A. Stevens (*N. Y. Med. Jour.*, Feb. 23, 1901) believes chloretone to be a valuable hypnotic in doses of ten to twenty grains, acting within a half to one hour, and seldom causing any ill effects either upon the stomach, the heart or general condition. It loses its power when used continuously, however, and in insomnia due to pain it is of little value. In mental excitement it is inferior to hyoscine and paraldehyde, and is not usually successful when the fever is above 102° to 103° F.

Convulsions in Scarlet Fever.—Nephritis is one of the most frequent severe complications following scarlet fever and is, no doubt, in most cases the cause of convulsions. H. F. Hayd (*Med. Rec.*, Feb. 23, 1901) reports such a

case in which three weeks after the scarlet fever began, with urine of a normal specific gravity and very little albumin and no casts, convulsions suddenly developed. Urea examinations should always be made in all suspected cases, as the specific gravity is not a reliable index. He believes that only the most digestible foods should be taken and, if possible, only milk, for gastric and intestinal fermentation alone may determine a convulsion if the kidneys are deficient in function. An abundance of water and nutrient enemata are preferable if there is much gastric irritability. To stimulate the kidneys, hypodermoclysis of two or three pints of decinormal salt solution is very valuable. The introduction into the bowels of a number of gallons of water ranging from tepid water to water at 80° F., if there is much fever, should be employed once or twice a day. Strychnine and digitalin are very valuable. Chloral and antipyrine, gr. v aa., by rectum and repeated when necessary, are very efficacious in assisting in the control of convulsions.

Treatment of Erysipelas.—N. G. Keirle, Jr. (*Phila. Med. Jour.*, Feb. 16, 1901) has had such success in the treatment of erysipelas by the following method that he no longer fears the disease. Of thirty cases, not a single one failed to yield to treatment in a few days, usually three or four. The affected area was first *enclosed* in a painted ring of tincture of iodine. The ring should be from two to three inches from the margin of the reddened area, and a sufficient number of coats should be applied to cause a slight desquamation of the upper layers of the skin. At the same time the whole of the surface enclosed in the ring should be covered with an ointment of ichthyol, about one dram to one or two ounces of vaseline. This should be covered with a piece of gauze and a hot stupe applied and changed every four hours. At the end of twelve hours the ointment should be washed off and a fresh coat applied, and, if the iodine has not had a sufficient effect, one or more coats should be applied. As is stated, three or four days of this treatment stopped the disease, the inflammation not crossing the painted ring.

Transmission of Infectious Diseases.—In the treatment of contagious disease the most important indication is to prevent its spread to other members of the family or community, and in order to successfully control epidemics, the means by which the disease is transmitted must be most thoroughly and scientifically sought out. The Health Department of New York City, so favorably situated, has undoubtedly taken the lead in such investigation and the results which A. H. Doty (*Med. Rec.*, Feb. 23, 1901) publishes are both valuable and practicable. One of the points upon which he lays especial stress is that the clothing actually worn by a well person, even after thorough exposure to the contagion, is seldom the means of communication. He cites much evidence to prove this, mentioning how infrequently the general practitioner carries the infection from one patient to another. In the epidemics of typhus fever and smallpox (1892 and 1893) there were 714 cases of the former and 842 of the latter disease. There were about 75 health officers frequently coming in actual contact with these patients, but, although 14 contracted typhus fever and seven died, in no instance did these officers transmit the disease to their friends or relatives. The greatest source of danger probably exists in not recognizing the mild and ambulant cases of contagious disease which may unintentionally transmit to many a more virulent type of the same malady. Careful investigation will almost always reveal the fact that there has been direct actual exposure to some infected person. The value of the knowledge and appreciation of such facts is, of course, most apparent. Every case of even suspected contagious disease must be isolated and carefully watched, and all the clothing and effects sterilized, preferably by the use of steam. The latter can usually be done only when the health department has a special apparatus. On the other hand, the wanton destruction of property which has merely been exposed to the diseased, especially cargoes from infected ports, is undoubtedly useless and most detrimental to commerce.

Periodical Insanity.—A. R. Defendorf (*Phila. Med. Jour.*, Feb. 16, 1901) discusses the symptoms, the frequency of occurrence, the different forms, the causes, and the prognosis of periodical insanity, and cites two cases in detail, one of the maniacal and one of the depressive form. In conclusion he says (*a*) that periodical insanity is a mental disease characterized by a definite symptomatology, course and outcome; (*b*) it, in point of numbers, is one of the most prominent psychoses; (*c*) the symptoms are sufficiently characterized to permit a differentiation from other forms of mental disease in the first attack, (*d*) and allow the forecast of the whole course of the disease, *i.e.*, (*e*) recurrence of attacks throughout the life of the individual, mostly of the character of the first, (*f*) with lucid intervals of varying length from weeks to years, except in very small percentage of cases, (*g*) without a tendency to mental deterioration, except in cases in which the attacks have been long, frequent, and severe, and even then it is of a light grade.

Typhoid in South Africa.—In his report on the Military Hospitals, J. W. Smith (*Med. Chron.*, Feb., 1901) says that the average of troops serving in South Africa during the year was 220,000, of whom one in fourteen was attacked by enteric fever and one in sixty died. Thus 7.11 per cent. acquired the disease and

the percentage mortality was 23.26. The number of cases therefore was over 15,000, but the death-rate corresponds very favorably with that of the London hospitals. Pneumonia and hemorrhages were rare complications, but perforation was present in about one-third of the fatal cases.

Gall-bladder in Typhoid.—The frequent occurrence of gall-bladder inflammation during or after an attack of typhoid has led to considerable effort to determine the relation between the two conditions. R. W. Marsden (*Med. Chron.*, Feb., 1901) has reported a case of typhoid with perforation of the gall-bladder, peritonitis and death due to ulcerations, in which the bacillus coli communis seemed to be the principal offender. The symptoms were characteristic, the Widal reaction was positive and a few small ulcerated Peyer's patches were found in the lower ileum. Typhoid bacilli were also present in the gall-bladder in moderate numbers, and he thinks are frequently the efficient cause of cholecystitis. The most important passage of these bacilli is probably through the blood, the liver, and the biliary ducts. On account of the frequency of typhoid infections of the gall-bladder, Chiari has suggested that the pouring of the bacilli with the bile into the bowel may give rise to a relapse, thus accounting for the possibility of a reinfection and relapse being due to the stimulating action of solid food upon the flow of bile.

Dilution of Milk for Infants.—In substituting cow's milk for woman's milk the chief source of trouble is usually the presence of a large percentage of proteids which are difficult to digest. A great difference of opinion exists as to whether the cow's milk should be diluted simply with water or with a cereal gruel. H. D. Chapin (*N. Y. Med. Jour.*, Feb. 23, 1901) claims that, no matter how much the milk is diluted, the casein of cow's milk forms hard, leathery curds when water alone is used; but, when a digested or dextrinized wheat-flour gruel is employed, the curds are soft and will easily pass through a small-meshed sieve. To prepare this gruel two tablespoonfuls of wheat or barley-flour are beaten to a thin, smooth paste with cold water. A quart of boiling water is added and the gruel is boiled for about fifteen minutes. A preparation of diastase is then added, made by soaking malted barley grains in water. The gruel is stirred until it becomes thin and watery. When this diluent is added to cow's milk the formation of large curds is practically impossible, and the digested starch which it contains is one of the forms of nutriment that are known to be rapidly absorbed and to promote the secretion of the digestive juices.

Acute Leucemia.—A peculiar case of the rare disease, acute leucemia, is described by A. Dennig (*Münch. med. Woch.*, Jan. 22, 1901). The patient came to the hospital with the symptoms of an advanced chlorosis and was treated for some time with Blaud's pill. Since she did not improve, a more careful examination was made of the blood, with the result that a steadily-diminishing number of red and a gradually-increasing number of white cells were found, together with the elements peculiar to acute leucemia. One hour before death, the relation of white to red cells was as one to two, the lymphocytes predominating. Characteristic symptoms, such as hemorrhage into the skin and from the mucous membranes and enlarged spleen and lymph-nodes, appeared only late or not at all. The bone-marrow on autopsy showed no macroscopic evidence of disease, in which respects the case differed from all others previously described. It was only the microscopic examination of the blood and the marrow, together with the rapid decline of the patient which gave a clue as to the true nature of the disease.

Strabismus.—After reviewing the various causes of heterotropia, J. H. Woodward (*Med. Rec.*, Feb. 16, 1901) urges that in a case of paralytic strabismus a thorough determination of the cause and extent of the lesion should be made by a competent person in order that immediate treatment may secure the improvement which is sometimes possible, syphilis and rheumatism being the most frequent amenable causes. Advancement of the paralyzed muscle may be considered in incurable cases. In non-paralytic strabismus the proper correction of the errors of refraction is the first indication, but only in a small percentage of cases glasses alone are sufficient. Operation is usually necessary, but it must be carefully and fully ascertained which is the offending muscle and whether it is overacting, contractured, overstretched or enfeebled. The one should be weakened by tenotomy, the other strengthened by the advancement of its insertion. Treatment of heterotropia should begin as soon as a child is old enough to wear glasses, and operations need not be postponed until the sixth or seventh year. A persistence of twenty years or more does not, however, contra-indicate interference.

Pathology of Blood-producing Organs.—C. S. Engel (*Münch. med. Woch.*, Jan. 22, 1901) asks whether constant relations exist between the condition of the blood and that of the bone-marrow in conditions in which these are pathologically altered. While normally the blood contains only one type of erythrocyte, two are found in the healthy bone-marrow, one resembling the normal red cell and called orthochromatic, and the other, polychromatic, with paler protoplasm. In diseased conditions the proportion of both varies considerably, as does also the relative amount of the various leucocytes, not however within definite lines which would allow a clue as to

the nature of the disease to be formed. The author has, however, found the following four conditions to be fairly constant: (1) Normal marrow, where the epiphyses contain red marrow, the diaphyses, fat. In the former both ortho- and polychromatic normoblasts are found. The blood only contains orthochromatic erythrocytes. (2) Insufficient marrow. Here the size and shape of the red cells are normal, but they are frequently much increased in number. The following changes may be found in the blood: (*a*) a normal number of red cells with diminished hemoglobin; (*b*) a diminished number of red with normal or diminished hemoglobin; (*c*) the presence of pathological cells, such as ortho- or polychromatic normoblasts or polychromatic erythrocytes; (3) metaplastic marrow, where the yellow marrow is partially or entirely red, and where megaloblasts and metrocytes, the latter a large orthochromatic cell with relatively small nucleus, are found. In the blood there are often megaloblasts and regularly macrocytes. (4) Aplastic marrow, a rare condition in which the red marrow is converted into fat and ceases to be hematopoietic. The blood contains no pathological cells, but red cells, and granular leucocytes are diminished without being replaced.

Failure of Cardiac Compensation.—In forming a proper estimate of the strength of cardiac action too much attention is usually paid, no doubt, to the valvular lesions as evidenced by the various murmurs and not enough thought laid upon the condition of the muscular walls. Pathologists have recently investigated more thoroughly the myocardial changes and, although their opinions still differ considerably, it is safe to say that a heart which has organic valvular disease no longer possesses a normal myocardium, since the latter has been involved in its parenchyma or interstitial tissue, or both, in various foci. Hypertrophy compensates for a time, but parenchymatous changes finally result in such weakening of the heart-walls that the reserve strength is lessened and an extra strain disturbs the equilibrium. M. Manges (*Med. Rec.*, Feb. 16, 1901) enumerates the causes of failure of compensation as follows: (1) Diminished general nutrition; (2) disturbance of local nutrition of the heart; (3) increased work of the heart; (4) functional cardiac disorder; (5) effects of improper treatment. Under the first heading may be classed not only those acute infectious cases and the many chronic systemic disorders, but also those ill-advised people who undergo reduction cures at Carlsbad and other resorts and thus frequently sacrifice cardiac compensation. Local nutrition is controlled by the coronary arteries and an arteriosclerosis situated here can be surmised only when part of a general arterial affection. Muscular overstrain, prolonged and violent athletic exercises frequently cause irreparable harm. As Schroetter suggests, people should exercise with their brains, as well as with their muscles. Purely functional disorders, mental excitement or emotion, may be of such serious import that the term "died from a broken heart" may be justly applied. Lastly the presence of a murmur does not mean that digitalis is needed, as so many physicians seem to believe. It is usually much better to avoid cardiac drugs unless their indication is clearly observed.

Liverpool School of Tropical Medicine Report on Yellow Fever.—An abstract of the interim report by H. E. Durham and the late W. Myers (*Brit. Med. Jour.*, Feb. 23, 1901) contains the following conclusions: (1) Sufficient search reveals the presence of a fine small bacillus in the organs of all fatal cases of yellow fever. We have found it in each of the fourteen cadavers examined for the purpose. In diameter the bacillus somewhat recalls that of the influenza bacillus; seen in the tissues it is about 4 micra in length. (2) This bacillus has been found in kidney, in spleen, in mesenteric portal and axillary lymphatic glands, etc., taken from yellow-fever cadavers directly after death. In the contents of the lower intestine apparently the same bacillus is found often in extraordinary preponderance over other micro-organisms. Preparations of the pieces of "mucus," which are usually, if not always, present in yellow-fever stools, at times may almost present the appearance of "pure culture." (3) Preparations of the organs usually fail to show the presence of any other bacteria, whose absence is confirmed by the usual sterility of cultivation experiments. (4) It is probable that this same bacillus has been met with but not recognized by three other observers. Dr. Sternberg has mentioned it; and it has also recorded the finding of similar organisms in material derived from Drs. Domingos Freire and Carmona y Valle; but he did not recognize its presence frequently, probably on account of the employment of insufficiently stringent staining technic. (5) The most successful staining reagent is carbolic-fuchsin solution (Ziehl), diluted with 5-per-cent. phenol solution (to prevent accidental contamination during the long staining period) immersion for several hours, followed by differentiation in weak acetic acid. Two hours' staining period may fail to reveal bacilli, which appear after twelve to eighteen hours. The bacilli in the stools are often of greater length than those in the tissues, and they may stain rather more easily; naturally the same is true of cultures. To facilitate matters at our last two necropsies a method of sedimentation has been adopted. (6) Pure growths of these bacilli are not obtained in ordinary aerobic and anaerobic culture tubes. (7) Some pure cultures have been obtained

by placing whole mesenteric glands (cut out by means of the thermocautery) into broth under strict hydrogen atmosphere. Investigations into the necessary constitution of culture media for successful cultivation are in progress. (8) Much search was made for parasites of the nature of protozoa. We conclude that yellow fever is not due to this class of parasite. Our examinations were made on very fresh organ juices, blood, etc., taken at various stages of the disease, with and without centrifugalization, and on specimens fixed and stained in appropriate ways. We may add that we have sometimes examined the organs in a fresh state under the miscroscope within half an hour after death. (9) The endeavor to prove a man-to-man transference of yellow fever by means of a particular kind of gnat by the recent American Commission is hardly intelligible for bacillary disease. (10) We think that the evidence in favor of the etiological importance of the fine small bacillus is stronger than any that has yet been adduced for any other pretended "yellow-fever germ." At the same time there is a much further work to be done ere its final establishment can be claimed. The acquisition of a new intestinal bacterium would explain the immunity of the "acclimatized."

THERAPEUTIC HINTS.

Nocturnal Incontinence.—Bommier classes his patients as follows: (1) Those who dream; (2) the apathetic, sleepy, and idle; (3) the ill-developed. The first class of patients have polyuria, are nervous, urinate frequently in the day time and at night dream that they are to urinate. Such require tonics, warm baths or douches, gradually made colder, and belladonna, antipyrin, gm. 1.0-4.0 (gr. xv-3i), chloral, gm. 0.30-1.0 (gr. v-xv), potassium bromide, gm. 1.0 (gr. xv), or extract of hyoscyamus, gm. 0.03 (gr. ½), are recommended. In the second class there is atony or atrophy of the sphincter, and there may be leakage during the day. Such patents sleep profoundly, so that the muscles become much relaxed. They need to make sleep less deep by small amounts of tea or coffee, to reduce the fluids taken at the evening meal, to be awakened at a fixed hour, best between midnight and one o'clock, and to be occasionally punished. Strychnine or fluid extract of rhus aromatica, gtt. v-xx, may be administered, though the latter's action is not yet well known. Faradism may be of use. The third class includes boys with phimosis, non-descent of testicle, congenital hernia, preputial adhesions and atresia of the meatus, and girls with adhesions of the clitoris, or between bladder and uterus so that the vesico-urethral orifice is drawn open, or with anal fissures, etc. In these patients, try to remove the cause, for medicine is of little or no use.

Silver Nitrate in Dermatology.—After trial of many of the recently introduced chemicals in eczema, J. C. Dunn (*Penn. Med. Jour.*, Jan., 1901) has returned to silver nitrate, using it in from one-per-cent. solution in acute forms, to the solid stick in old and thickened patches. In psoriasis, erythema, acne, especially the pustular form with marked erythema or inflammation, herpes zoster, the various tineæ, contagious impetigo, and lichen planus; it is at least as effective as chrysarobin or salicylic acid, and is often better borne. It is sedative, astringent, antipruritic and seems to have an alterative effect on the nutrition of the skin.

Nasal Neurosis.—One sees women having frequent attacks of sneezing both summer and winter, a thin watery discharge, and a tendency to obstruction of a nostril, sometimes one side sometimes the other. On examination there is no hypertrophy, no permanent obstruction, but simply a turgescence of the membrane over the turbinate. Such are treated by Samuel B. Dabney (*Pediatrics*, Feb. 15, 1901) with

℞ Ac. arsenosi.....gm. 0.06 (gr. 1)
Strych. sulph.....0.04 (gr. ⅔)
Ext. bellad. .....
Zinc. phosphid., aa.....0.25 (gr. iv)
Ext. gentian., q. s.....ad pil. No. XX.

One three times a day, and the local application of menthol.

Phototherapy.—Leredde has used the light from an arc-lamp in parasitic and other skin-diseases. The chemical rays kill bacteria and stimulate the cells of the skin, and are applied by condensing lenses for an hour or more twice a week. Occasionally erythema and pigmentation result. The diseases treated with success are lupus, acne vulgaris, acne rosacea, rhinophyma, alopecia areata, some cases of epithelioma, and sycosis.—*Bulletin général de Thérapeutique.*

Gonorrhea in the Female.—Alfred Roulet (*Ann. Gynec. and Ped.*, Feb., 1901) cleanses the vulva with bichloride solution, 1-10,000, or boric acid, 4 per cent.; keeps patient in bed, and gives potassium citrate, gm. 0.7 (gr. x), every two hours. A solution of protargol, gm. 0.06-0.7 to 4.0 (gr. i-x to 3i), is applied to the urethra, and a 2-per cent. solution swabbed or sprayed over the vaginal walls. At bedtime the following suppository is used if necessary:

℞ Protargol.....
Europhen, aa., gm. 0.7 (gr. x).
Ol. theobrom., q. s., ad. suppos. No. X.

Neuralgic Dysmenorrhea.—To treat gout rheumatism, malaria, anemia, or other constitutional dyscrasia, apply a capsicum or mustard plaster over the painful area, and do not give morphine, says E. C. Underwood.—*Annals of Gynecology and Pediatry.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

RECENT OBSERVATIONS ON DIPHTHERIA.

The clinical features of diphtheria have been so considerably modified within the last few years by the use of antitoxin that the classical description of Bretonneau must, indeed, sound a strange note to those whose experience with this disease dates back hardly more than five or six years. Any recent careful study of this curse that struck terror to the hearts of our fathers must then be not only of special, but general interest. An extremely interesting paper just published by Dr. Fred Grant Burrows (*American Journal of Medical Science,* February, 1901) summarizes the results of the writer's experience with 2,093 cases of diphtheria treated at the Boston City Hospital from August, 1899, to a corresponding period in the following year.

From being the most fatal of the acute infectious diseases, with a death-rate of from 30 to 50 per cent., its mortality has so greatly decreased that it is scarcely a more important factor in the total death-rate of Boston than typhoid fever. The last and Twenty-Seventh Annual Report of the Board of Health of that city shows a mortality of 9.7 per cent. Of the 2,093 cases treated, 131 proved to have a mixed infection and 1,962 were uncomplicated. Among the latter 240 died, giving a mortality-rate of 12.23 per cent.; but of those that died 69 were moribund when admitted and died within twenty-four hours of admission.

The majority of those admitted were females, but no noteworthy difference in the death-rate of the sexes was observed. Most of the patients were under fifteen years of age. For these the death-rate was 14 per cent.; and for those above that date it was only 2.85 per cent. An examination of the tables given by Dr. Burrows shows a decreasing death-rate from infancy to adult life.

A study of the membrane distribution shows that, although quite variable, both tonsils were generally the seat of election; occasionally the uvula, posterior pharyngeal wall, palate, lips, tongue, epiglottis, cheek, external auditory canal, eye, labiæ majoriæ and minoræ, nostrils and skin, were affected, sometimes alone or associated with membrane-formation elsewhere. It is important to point out in this connection that the diphtheritic membrane merely represents in a general way the amount of local reaction wherever it may be situated; but its amount or distribution bears no definite relation to the quantity of poison absorbed and the consequent existing toxemia—often enough severe and even fatal cases of diphtheria are seen without any membrane whatsoever. It is therefore, as Dr. Burrows says, but one of the guides in the administration of the antitoxin.

There is one extremely important point worthy of mention in connection with the bacteriological diagnosis of the disease The observation is, however, by no means new, being perfectly well known to students of diphtheria. Some of the worst cases, studied by the writer, with thick and extensive false membrane, persistently gave negative cultures until the membrane began to disappear, when it became possible to take cultures from the mucous membrane of the throat, and many diphtheria bacilli would be demonstrated. With regard to the bacteriological diagnosis, experience has shown it invaluable and necessary, but, as is properly stated in this paper, it is often impossible to wait for bacteriological confirmation. In such cases the clinical picture should be the basis of judgment and, at all events, when in doubt experience has shown that it is far safer to administer the antitoxin and otherwise treat as a case of diphtheria.

Over one-half of the cases showed evidence of cardiac disturbance at some time during the course of the disease: usually it proved slight

and transitory. Murmurs were not uncommon. Irregularity of heart-action was also frequent and, as noted by others, most conspicuous in those cases in which there has been nasal diphtheria. Rotch more than ten years ago explained this by pointing out the extremely abundant supply of lymphatics to the nasopharynx.

A little over twenty-eight per cent. of the cases in which the urine was examined showed albumin, in no instance above one-fourth of one per cent. Nephritis was uncommon.

In this series of 1,902 cases, 337 had laryngeal stenosis; of this number, 213 were intubated and 124 were relieved by the antitoxin without intubation. In the laryngeal cases the death-rate was 31.4 per cent. The early cases without operation showed a mortality of only 8 per cent., whereas in the operative (and late) cases it jumped up to 45 per cent. Dr. Burrows strongly advocates the abandonment of primary tracheotomy in the treatment of simple diphtheritic laryngeal stenosis; in this he is supported by McCollum of Boston and others. Among the complications observed were middle-ear disease (3 per cent.), palatal, oculomotor, and deltoid paralyses, and hemiplegia in one instance. The patellar reflexes were often found diminished. On the whole, the nervous complications were fewer than before the administration of antitoxin. Of the cases that died 71.6 per cent. succumbed in the acute stage of the disease; the others died in the secondary stage, or later of some other and complicating condition.

As already shown, the amount and distribution of the membrane cannot be taken as an index upon which to base the administration of antitoxin; in this the experience of others was again conclusively demonstrated by the experience at the Boston City Hospital. At the hospital 4,000 unit-doses are given and repeated every four hours as long as may be necessary; in a few very severe cases this amount was even exceeded. The earlier the administration of the antitoxin, the better the results.

PRIVATE SANATORIA FOR CONSUMPTIVES.

The power of an idea is stronger than any power of legislature. It would be impossible to legislate consumption out of existence, for the reason that there are too many consumptives for the State to take care of. Therefore there is the greatest need for individualized effort on behalf of charitable and philanthropic people for the suppression of the disease. The effort that various societies are making to protect the members of their own community from spreading the disease is one of the best expressions of the sentiment of common sense and practical hygiene of the age. In Dr. Knopf's article published in this week's issue of the Medical News, the situation is plainly set forth. It is the incipient cases that must be treated by rest and fresh air, and it is the personal friends of the poor, the workers in clubs, settlements and tenement neighborhoods, who must report the cases, get them out of their environment, and save their lives and protect their families from infection. By the increase of societies for the establishment of sanatoria for tuberculosis patients among the poor the end may be slowly accomplished, and the crowded quarters of large cities will gradually be cleansed of this, the world's plague. Nothing, however, but sentiment arousing citizens to a sense of their personal danger and personal responsibility will do this. Therefore, we look with the warmest approbation upon such societies as that of the Stony Wolde Sanatorium; and upon every effort to bring the social aspects of the disease before Society.

EXTIRPATION OF THE HYPOPHYSIS CEREBRI.

In recent years the attention given to the functions of the thyroid gland, physiologically, caused at the same time, both on account of its peculiar anatomical situation, of the seeming impossibility of operation upon it, and also of its mysterious functions, an intense interest to be taken in the hypophysis cerebri.

It has been observed that stimulation of the hypophysis produced changes in the blood-pressure and the conclusion was drawn that this gland produced a secretion which affected the distribution of the blood through the brain. Observers obtained an extract of the gland which upon intravenous injection regularly caused changes in blood-pressure. Mairet and Bosc are said to have produced an increase in the number of epileptic attacks in affected persons by means of this extract. Some of the extravagant ideas relating to the hypophysis have been sceptically received and in order to verify what there is of truth in them F. F. Friedmann and Otto Maas describe the operation of extirpation undertaken by them on animals in the *Berliner klinische Wochenschrift* (Dec. 24, 1900).

Previous operations had always resulted in the

quick death of the animal, and this was attributed to the fact of the part necessary to life played by this gland. The authors describe their operation as follows. The animal (in all their cases cats were used) is anesthetized with ether, the extremities and head immovably fixed. The jaws are opened as wide as possible and the lower mandible bound in this position. Then the tongue is pulled out as far as possible and kept in position by means of a clamp, leaving the hard and soft palate. After clearing the mucous membranes, an incision is made exactly in the median line of the middle third of the soft palate. The edges of the cut are well retracted and the wound sponged free of blood. This enables one to perceive the base of the skull at the body of the sphenoid bone. A second incision into the bone exactly in the median line and retraction of the periosteum and mucous membrane lay the bone itself open to view. In the center of this cut a small bleeding cavity is exposed which is enlarged by means of a spiral bore, which finally penetrates the bone absolutely in the median line. This opening is gradually enlarged, small pieces of bone being carefully nipped from the posterior border. The porous bone on either side is gently crowded back by means of a bone chisel and the slight crushing which ensues is sufficient to allay the venous hemorrhage which has been taking place up to this time from these porosities. Sufficient clearing having been accomplished, the hypophysis covered by dura is seen, a grayish white mass lying directly at the opening. The dura is incised in the exact median line and the incision must be superficial or else hemorrhage from the pia will result. A blunt sound is introduced into the dura incision and the membranes surrounding the hypophysis gradually separated thereby from the mass itself. Finally, and with great care the separation of the hypophysis from the base of the brain is carried out in the same way and the hypophysis is lifted out with a fine forceps. The cerebrospinal fluid which, mixed with blood, slightly oozes out must not be removed as its presence hastens the clot-formation. The incision in the soft palate is then closed with four or five silk sutures. The great danger in the operation is that the cavernous sinus may be injured by any incision not made exactly in the median line—a *faux pas* succeeded by inevitable death.

In eighteen cases the authors were successful in their operation. The animals were killed three or four months afterward, but a few died earlier from septic infection and hemorrhage. In one animal, in which the entire gland was removed, the result was perfect. The animal regained full health and strength and was in full possession of all its faculties. In neither the cases of total extirpation nor in those of partial extirpation was a gain or loss of weight characteristic. These few facts enable us, however, to declare emphatically that the hypophysis cerebri is not a vital organ. If it possesses any important functions at all, these latter must be carried on by other organs after extirpation of the hypophysis. Postmortem examination revealed no change in any other organ which could be held responsible for the loss of the hypophysis. The examination of the urine of the animals operated upon gave no trace of albumin. Glucose was present, however, in all of the cases. Those that lived sufficiently long after the operation nevertheless gave a constantly-decreasing sugar reaction until, finally, no trace could be found. The glucose was probably the result of the ether narcosis.

Finally, it may be remarked that this operative procedure might be serviceable in human beings, not only for the rare hypophyseal tumors supposedly related to acromegaly, but also for inflammations and other pathological conditions situated at the base of the brain. Drainage of the exudate in tuberculous meningitis is a case in point. The authors operated on cadavers of children and certify as to the practicability of such operations.

ON THE ETIOLOGY OF YELLOW FEVER.

The Liverpool School of Tropical Medicine has been investigating the subject of yellow fever and through its officers Drs. Herbert E. Durham and (the late) Walter Myers there is presented (*British Med. Journ.*, Feb. 23, 1901) an abstract of their investigations. It is noted in passing that both investigators contracted the disease and in one of them, Dr. Myers, it proved fatal.

Among the most interesting of their findings was a fine, small bacillus found in all cases of yellow fever, which bacillus does not agree with any other which has been described as an etiological factor. They mention that Sternberg had seen it, but did not recognize its universal presence. Thus far the investigators have not been able to isolate and grow this organism either under aerobic or anaerobic

conditions. They were unable to find any protozoon in any of the cases, although special search was made with this idea in view and the conclusion is reached that this class of parasite probably has nothing to do with yellow fever.

In view of the recent experiments of Drs Reed and Carroll, the opinion of the workers of the Tropical School relative to the mosquito theory is of interest. According to them, the transference of a bacillary disease solely by means of insect parasites is an assumption difficult to understand. Moreover, their own experiments do not seem to bear out the American investigators and they further maintain that certain endemiological conditions are not satisfied by such an assumption.

That yellow fever may be conveyed by the mosquito is readily understandable, but even with the evidence, so well set forth at the Pan-American Congress, with the workers of the Liverpool Tropical School we are not yet prepared to accept the conclusions reached by the American investigators.

THE CAUSE OF SMALLPOX.

The history of the search for the etiological factor of smallpox is one of much interest because of the extreme elusiveness of the agent in question. Bacteriologists have seemed to have come to the opinion that a bacterium is not the cause of the disease, or, if it is, it is one too small for the present powers of the microscope and as yet uncultivable.

Within recent years investigators have scanned the zoological field, and Dantzig in 1868 first described a corpuscle, which Renaut of Lyons and Van der Loeff of Amsterdam, in 1881 and 1886 respectively, held was probably a protozoon. More precise ideas were given by L. Pfeiffer in 1887-1891 in his studies on "Die Protozoon als Krankheits Erreger."

One of the latest studies is that of M. Funck of the University of Brussels (*Brit. Med. Jour.*, Feb. 23, 1901). He describes, in a preliminary note, a protozoon, occurring in three different forms which, he maintains, are the true agents in the causation of smallpox. He has named it the *Sporidium vaccinale* and credits Pfeiffer as the first to accurately describe it.

As yet the presentation of the author's studies is too incomplete to hazard an opinion of the merits of the work. We here append his conclusions without comment: (1) Vaccinia is not a microbic disease. (2) It is caused by a protozoon easily found in all vaccine pustules and in all active vaccine. (3) The inoculation of this protozoon in a sterile emulsion reproduces in susceptible animals all the classical symptoms of vaccinia. (4) This inoculation renders the animals refractory to subsequent inoculation with vaccine. (5) The variolous pustules contains a protozoon morphologically similar to that in the vaccine. (6) It follows that variola and vaccinia are two identical affections, that vaccine is nothing more than an attenuated form of variola, and that consequently the immunity to smallpox which vaccination confers does not form an exception to the general laws of specific immunity.

ECHOES AND NEWS.

NEW YORK.

Mount Sinai Hospital.—Examinations for vacancies in the house staff of this hospital will be filled by competitive examinations to be held at the hospital on March 28, 29, 1901. Graduates or those students graduating before July 1, 1901, are eligible. Applications in writing should be made to Dr. J. Rudisch, Mt. Sinai Hospital, New York.

Stony Wolde Sanatorium.—The Stony Wolde Sanatorium Building Committee met with persons interested in their philanthropic work at the residence of Mrs. Robert Maclay Bull, No. 40 East Fortieth street, last Tuesday afternoon at 3 o'clock. Short addresses were made by the Rev. Dr. William S. Rainsford, Dr. Edward G. Janeway, and Miss Wilkie, of St. George's Deaconess House .

Clairvoyance, But Not for Money.—The Assembly Public Health Committee has once more amended the Bell Anti-Christian Science bill reported it for reprinting. The bill has now been drafted so that it will not affect gymnasium instructors and will provide that Christian Science, clairvoyance, spiritualism and other cures may be practised gratuitously, but where they are utilized for gain they will be deemed to be a violation of the Penal Code. In this shape it is expected that the committee will report the bill favorably.

New York Academy of Medicine.—At the meeting of the Section on Surgery Monday evening, March 11th, Dr. Fred Whiting will read a paper on the Indications for the Ligation of the Jugular Vein in Sinus Thrombosis; with Illustrative Cases.

The Section on Otology will meet Wednesday evening, March 13th, and the following papers will be read: Tinnitus Aurium; Some

Remarks on its Causation and Treatment, by Dr. Thos. J. Harris; Tympanic Vertigo, due to Obstruction in the Eustachian Tube, by Dr. Wm. P. Brandagee.

At the meeting of the Section on Pediatrics on Thursday, March 14th, papers will be read by Drs. Finley Bell, Martha Wollstein and John Lovett Morse of Boston, on the general subject of Typhoid Fever. Dr. Morse will speak on the Value of the Widal Reaction.

The Section on Orthopedic Surgery will hold its stated meeting Friday, March 15th. Patients, instruments, etc., will be presented by Drs. A. B. Judson, Henry Ling Taylor, W. R. Townsend, Homer Gibney, George R. Elliott and S. A. Twinch.

The following have been recommended for resident fellowship: Drs. William Seaman Bainbridge, Edwin Holmes, Lester Mead Hubby, Samuel Murtland, Louise G. Rabinovitch and Arnold Sturmdorf.

PHILADELPHIA.

Presbyterian Hospital.—The Board of Trustees has created a Department of Laryngology and Rhinology and placed Dr. A. B. Cleveland in charge.

Pennsylvania Hospital.—This time-honored institution will, early in June, reach the one-hundred-and-fiftieth anniversary of its founding. A committee consisting of two members of the Board of Managers, the Superintendent of the Insane Department, and the President of the Medical Staff, has been appointed to make arrangements for a fitting celebration of the event.

Death From Overdose of Potassium Chlorate.—Mrs. Mary C. Knauff, twenty-five years of age, died last week apparently from the effects of potassium chlorate taken to relieve a sore throat. One ounce of the drug was taken the first day and half an ounce the following day. Alarming symptoms afterward developed, and despite the efforts of the physician who was called, the woman died. Postmortem examination was not obtained.

Dr. Osler Visits Philadelphia.—Dr. William Osler, of Johns Hopkins University, addressed the students of Jefferson Medical College Monday evening, March 4, on the philosophy of the "Power of Sympathy." The discovery of the old chemist was alluded to and then reference was made to the power of suggestion in modern medicine. Following the address Dr. Osler was the guest of honor at the annual banquet of the Hare Medical Society.

Smallpox at State Capital.—New cases of smallpox are developing at Harrisburg and the Sanitary Committee of Councils has ordered the vaccination of all persons not thus protected. The condition of affairs is an interesting one at this time, when antivaccinationists are making vigorous efforts to secure the repeal of the compulsory vaccination law. A memorial urging this action has been signed by thirty-six physicians of this city and Chester, who express the opinion that the theories upon which the law is based are antiquated. They are opposed to compulsory vaccination on account of its proven inability to protect and as "an unwarranted outrage on the personal rights of the individual guaranteed by the Constitution."

Primary Carcinoma of Appendix.—Drs. R. H. Harte and R. N. Wilson, Jr., report this case from the Pennsylvania Hospital. The patient was a woman of twenty-four years who had at intervals appendicular symptoms and also pain in the right lumbar region. The appendix presented no tumor, but its lumen was obliterated and a carcinoma one-half centimeter in extent was situated near the middle of the organ. The condition is believed to have been impossible of diagnosis before operation. Dr. Wilson believes that the seriousness of the prognosis in these cases has been exaggerated. If it is as unfavorable as is generally supposed, the propriety of at once removing every appendix when symptoms present is to be considered.

Home Treatment of Tuberculosis.—Dr. Lawrence F. Flick presented an admirable paper on the above subject at a recent meeting of the County Medical Society. The three ends to be attained are the restoration of the physiological functions of the body, hypernutrition, and the conferring of immunity. General practitioners should be more alert in making the diagnosis, an important early symptom being indigestion, persistence of which should lead to physical examination of the lungs. When the diagnosis is made three things are to be done. First, acquaint the patient with his exact condition, as this may be necessary to secure his coöperation in the treatment; second, explain to him that successful treatment means a long and persistent struggle, lasting perhaps from three to five years. Patients are often not cured when they seem to be and treatment should be kept up after symptoms subside; third, lay down a routine for governing the patient's life as to food, exercise, clothing, etc. These patients can often take large quantities of food, three to six quarts of milk and six to twelve raw eggs daily. Regarding medication, antidiaphoretics and opium are avoided. The iodine compounds are first in value. Next is creosote which is given in hot water before meals in doses reaching 50 drops three times a day. Strychinine, arsenic, phosphorus, digitalis, and iron are of value. Use any drug that will help any organ. One of the greatest difficulties in the treatment is the occurrence of complications, as colds, influenza, or pneumonia, either of which may cause a recrudescence. In event of their occurrence absolute

rest in bed for several weeks must be insisted upon. The results of six years' work by Dr. Flick shows 18 per cent. of cures, with varying degrees of improvement in 55 per cent.

CHICAGO.

Appointment of Dr. Stanton.—Dr. S. C. Stanton has received the appointment of Contract Surgeon in the United States Army, to be stationed in Chicago. He has been doing work in connection with the Government's recruiting station here for some time.

Chicago Laryngological and Climatological Society.—At a meeting, held February 28th, the following officers were elected: *President*, Dr. Wm. E. Casselberry; *Secretary and Treasurer*, Dr. John E. Rhodes; *Council*, Dr. Wm. L. Ballenger, Dr. Otto Stein, and Dr. Melville T. Hardie.

Ravages of Venereal Diseases.—This subject was discussed at the regular monthly meeting of the Physicians' Club of Chicago, held February 25th.

Circumcision in Restricting the Spread of Syphilis.—Dr. Harold N. Moyer spoke on this subject. In view of the doubtful efficacy of registration and examination, the speaker earnestly invited attention to an operation which is simple, devoid of mortality or disfigurement, against which nothing can be said, and which has as a result, if universally applied, a lessening of the most disastrous of venereal diseases from 50 to 75 per cent., namely, circumcision.

Diminution by Education.—Dr. Edmund Andrews said that in educating the public the medical profession can sometimes work through other professions. Physicians can do a great deal of good through the clergy. The clergy have a powerful influence in every community, so that in educating the public as to these diseases and their ravages, it is important to secure their coöperation. Morality and sanitary science are natural allies and ought to march forward hand in hand.

Special Hospitals.—Dr. Joseph Zeisler regretted that there is not a hospital in Chicago for the treatment of venereal diseases. Vienna has a hospital in which there are six hundred beds for the management and treatment of venereal affections. The educational value of such hospitals, aside from the treatment and care of patients, would be immense to physicians. Students would have the advantage of seeing a large amount of material and of receiving from eminent men instruction in regard to venereal diseases.

Can Venereal Diseases Be Lessened?—This phase of the subject was discussed by Dr. J. Clarence Webster. He said there was no more important factor in producing disease, misery and distress in women than the gonococcus. The rank and file of the profession look upon gonorrhea in women as did our forefathers. A chronic gonorrhea may be apparently cured, but there may remain a latent condition. In females the gonococcus acts only on the urethral mucosa primarily and on the cervical mucosa. It rarely attacks the vagina or the vulva. In young children a typical gonorrheal vaginitis or vulvitis may be observed. The ordinary routine treatment of gonorrhea in the female by douches, etc., is responsible for an enormous amount of inflammatory mischief occurring elsewhere.

Legislative Control.—Judge Lorin C. Collins feels that something should be done toward legislative enactment for the control of these diseases, and he believes a move on the Legislature of the State, with such a body as the medical profession back of it, would be a great educational force which would lead to the dissemination of information on these subjects and eventually bring about some good. But any measures, however, for the control of these diseases would have to be handled in a careful, conservative way in order to meet with the approval of State legislators. Dr. L. Blake Baldwin said that a small hospital had been established for the treatment of venereal diseases in Chicago, and that a public-spirited citizen had already contributed $3,000 toward it. There are at present forty patients in the institution suffering from either gonorrhea or syphilis, or both.

Menace in Dowie Faith.—A man by the name of Carstensen fell down the basement stairs a short time ago while carrying a pail of coal, fracturing five ribs. He was taken upstairs and until his death was without medical aid. He was a believer in the teachings of Dowie. A Coroner's jury reached the following conclusion: "From the evidence presented, we, the Jury, believe that if medical aid had been rendered the deceased would have recovered from his injuries, and that he would have certainly been spared the physical agonies which he evidently suffered; and we recommend that some law be enacted which will compel medical examination by licensed physicians in cases of accidents or external violence."

Warning by the Health Department.—The City Health Department has issued a warning that debilitating causes of all kinds, particularly alcoholism, predispose to attacks of pneumonia. Exposure to sudden changes of temperature should be avoided. The feet should be kept dry and warm and the throat and chest well protected. Fasting rather than indulgence should be adhered to. The higher the bodily condition the less favorable is the growth and virulence of the pneumonia germ. The laboratory examinations show a notable decrease in the findings of the influenza bacillus, indicating that the disease is declining. On the other hand, the organism of pneumonia is found in increasing numbers, and there is a

strong probability that, with the usually trying March weather, there will be a marked increase in the prevalence of this malady.

Prevention of Insanity.—At a meeting of the Chicago Society of Internal Medicine, held February 25th, Dr. D. R. Brower read a paper on this subject, in which he said that insanity has increased out of all proportion to the increase in population during the last thirty or forty years. The statistics of Great Britain show that the proportion of insane to the whole population in 1860 was 1 to 523, in 1890 1 to 320, and in the State of Illinois the proportion of insane to the population was about 1 to 400. Preventive measures must come from the States. The State has assumed the care and maintenance of the insane. Indeed, it has made it a criminal offence for anyone to restrain them without the consent of its courts, and inasmuch as the State has assumed this great responsibility, it is its duty, in the interests of altruism and of economy, to use every possible means for the prevention of insanity, to find out how this may be done, to educate the people and to enforce methods of prevention. The State should, through the State Board of Health, furnish the people with information that they can comprehend as to the causes of insanity and of methods that may be applied for its prevention, and the State should be as ready with the same paternal power it uses in smallpox, cholera, etc., to enforce those methods that have the approval of the medical profession. The State should make its insane hospitals schools for instruction in insanity. It should by competent authorities select by competitive examinations senior students in medicine from medical colleges and place them in hospitals for the insane as internes. These internes should remain at least one year, receiving board, lodging, and a small gratuity at the end of the service. By adopting such methods at least thirty physicians every year in Illinois with mental attainments of a high order will be sent forth with a good clinical knowledge of insanity, its prevention and treatment, and become so many prophylactic centers in as many communities; but a few years would be necessary to have from one end of the State to the other an abundance of skilled medical men competent to solve this great problem. The State should assist in providing treatment for carefully-selected cases in wards connected with the hospitals now to be found in every city and almost every town in the State, and the requirements for admission should be the same as those which apply to any other disease. Heredity as a factor in the production of insanity can be reached radically by only two methods, first, the regulation of marriage, and second, the asexualization of degenerates, but in order that either one of these methods may be established there must be a great deal of educational work done by the medical profession.

GENERAL.

Kentucky State Medical Society.—The forty-sixth annual session of this Society will be held in the city of Louisville May 22, 23, 24, 1901.

American Neurological Association.—The twenty-seventh annual meeting of this Association will be held in Boston on Wednesday, Thursday and Friday, June 19, 20 and 21, 1901. The meetings will be held at the Boston Medical Library. Members are requested to send the titles of papers to be presented by May 20th.

Grace Hospital of New Haven.—Following the summary dismissal a few days ago of Dr. Arthur S. Cheney, head of the surgical staff in Grace Hospital, on the charge of taking fees from a hospital patient, comes the announcement to-night that his father, Dr. Benjamin H. Cheney, chairman of the board of physicians and surgeons of the same hospital, has resigned. Coupled with the same announcement is another that his mother, Mrs. B. H. Cheney, chairman of the woman's board of Grace Hospital, has also resigned.

Medical Examination of Engaged.—The Senate passed a bill March 4, 1901, which is designed to limit divorces in Indiana by preventing ill-chosen marriages. The bill provides for the appointment of a commission by the Governor which shall be composed of two women, who are mothers, two physicians of conceded ability, and one attorney of high standing, who shall prepare rules for the government of officers in the issuance of marriage licenses and of ministers in performing ceremonies; and examinations shall be made of all applicants for licenses, and no marriages shall be celebrated in the State unless the requirements are complied with. The idea back of the bill is to require physical examinations and an inquiry into the parentage of the applicants to the end that their union may be prevented in the event that conditions inimical to the welfare of society should be foreshadowed as a result of marriage.

Obituary.—Dr. Richard J. Dunglison died at his home in Philadelphia Monday, March 4th. He was a son of Prof. Robley Dunglison and a grandson of Dr. John Leadam, a celebrated London surgeon. Dr. Dunglison was born in Baltimore, Md., November 13, 1834, was graduated from the Central High School and the Collegiate Department of the University of Pennsylvania, receiving the degree of A.B. in 1852 and A.M. in 1855. In 1852 he took up the study of medicine under his father's direction, and, after a four years' course in the Jefferson Hospital Medical College, graduated from that institution in 1856. He was the edi-

tor of "Dunglison's Dictionary," originally written by his father, Dr. Robley Dunglison, and many other medical works of reference. He was acting assistant surgeon in the army from 1862 to 1865, and executive officer of a local army hospital during the closing years of the Rebellion. He was a member of the County Medical Society, Mutual Aid Association, State Medical Society, American Medical Association, International Medical Congress and many similar organizations, in nearly all of which he held office.

The Law and the Physician.—According to the *San Francisco Examiner* a physician of that city was ordered to pay $2,000 damages by the Supreme Court. Evidence showed that over a year ago he was called to attend Mrs. Margaret A. Lathrope. An operation was deemed necessary by him. Her screams interfered with his application of the necessary instruments. He finally said that if she "did not quit he would quit." And leave he did, although the patient was in agony. The husband followed the physician to the door, begging him not to go. Refusing to come back, it was over an hour before another doctor was obtained, the woman in the meantime suffering dreadfully. The other surgeon performed the operation, saving the mother's life at the expense of that of the child. Mr. and Mrs. Lathrope sued the physician and got a verdict for $2,000 in the Superior Court. The case was appealed and the Supreme Court upheld the decision of the lower court, as follows: "It is the undoubted law that a physician may elect whether or not he will give his services to a case, but having accepted his employment, and entered upon the discharge of his duties, he is bound to devote to the patient his best skill and attention and to abandon the case only under one or two conditions. First, where the contract is terminated by the employer, which termination may be made immediately. Second, where it is terminated by the physician, which can only be done after due notice and an ample opportunity afforded to secure the presence of other medical attendance. * * * He can never be justified in abandoning it (a case) as did this defendant, and the circumstances show a negligence in its character amounting well nigh to brutality."

CORRESPONDENCE.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE AMERICAN MEDICAL ASSOCIATION.

To the Editor of the Medical News:

Dear Sir: In view of the recent paper by Dr. Frank Van Fleet of New York City, discussing frankly, but temperately, the relation of the double State and county organization of the regular medical profession in this State, it may seem that further writing on the same general subject is unnecessary, but as it has been for some time my intention to prepare such a paper, and as the standpoint of any two writers is somewhat different, additional consideration of this subject may be allowable.

Whatever is said on this subject depends so largely on the attitude of the writer that it is proper at the outset to place before the reader a declaration of platform. The old bitterness which led to the establishment of a second set of regular medical organizations in the State of New York antedates the present writer's active professional life, and he has been the recipient of courtesies from both organizations and he enjoys the friendship of men prominent on both sides of the dissension. To this degree impartial, he is strongly biased by a veneration for whatever is ancient and established, by a corresponding dislike of all schism, religious, political or professional and by a deep regret that the framers of the Constitution of the United States were not able, as was seriously considered at the Constitutional Convention, to do away entirely with the sovereign states and to establish a central national government. Thus, he is at the same time as loyal to the State Society as the older men who advocated a policy which inevitably led to the separation from the National body and as anxious for representation in the latter as the most energetic seceders who formed the Medical Association of the State of New York.

Since all privileges of a scientific and social nature attaching to the American Medical Association are open to every medical practitioner of the country in good standing, who is not avowedly in opposition to the principles of the general medical profession—alias Allopaths—and since the medical politics of the Association to the ordinary mind are not worth the trouble and expense involved, it may well be asked, Why consider seriously the privilege of delegate membership at all? The writer is sufficient of a Yankee to answer this question with two others: Why does the average American, whose political privileges amount practically to casting a ballot once a year for one of two sets of men selected by forces entirely beyond his control, value his franchise so dearly? and, Why does the chaste bachelor have a sentimental objection to emasculation? It certainly is not pleasant for the medical man from New York to feel that he is debarred from the privileges enjoyed by members from other States and that he must either abandon his franchise in the American Medical Association or obtain it by membership in a private or semiofficial State organization.

The breach between the New York State Society and the National organization was due to the efforts of the former to secure decent requirements as to medical training and the education of medical students. To obtain leg-

islation, it was necessary to combine with Homeopaths and Eclectics and, more or less formally, to recognize these schools. That the action of the Society was wise has been amply proved by the results not only in New York, but in other States which have followed the example and, strangely enough, in one or two instances without incurring the displeasure of the American Medical Association, or at least without the loss of representation of their State societies in the National body.

Indeed, the exasperating feature of the whole matter is the utter needlessness of the schism at present existing in our State. A double State and county organization of medical men is exactly as useful and desirable as two tails on a cat. The medieval notion that one must be in full sympathy with every detail of an organization, or must get out and establish an organization of his own, has been the curse and scandal of Christianity, has been the cause of most of the political troubles of the world, and it is the main evil with which the medical profession has to contend. A little tolerance and indifference, a couple of generations ago, would have deprived the school of homeopathy of its excuse for existence and would have obviated one of the marked weaknesses of the medical profession. The same spirit in the late seventies and early eighties would have avoided the greatest source of discord in the regular profession of our State.

If there existed a genuine and marked difference of principle between the two sects of regulars in New York, one might view the situation with equanimity, but no such difference exists. The adherents of the Society have recognized Homeopathy and Eclecticism only to the degree of making a compromise which was a necessary step toward an end the utility of which every physician and layman must admit. On the other hand, the adherents of the Association seem to feel that it is a theory and not a condition that confronts them. Many of the most active supporters of the Association consult freely with Homeopaths, and it is broadly hinted that some of its members even seek such consultations. On signing the application blank for the American Medical Association, the writer remarked, "There, I suppose I have committed perjury for I certainly shall not refuse to give advice for a patient in an emergency, even if the attendant is a Homeopath—although I would surrender a case rather than call a Homeopath in consultation." "Oh, no," rejoined one of the stalwarts, "we simply confess that consultation with a Homeopath is an absurdity; we don't promise not to hold it."

The worst feature of the whole matter, at present, is that at the very time when a spirit of toleration and harmony is rapidly developnig in the profession, and when there is needed only a little patience until a few desirable funerals have taken place, so that the obstacles to reunion of the State Society and the National Association may be removed, the State Association is making the most strenuous attacks on the State Society and its county branches. Specious appeals are being made to physicians, especially young men who do not realize the conditions, to leave the legal medical organizations of the State. It has recently been made impossible to secure delegate membership in the American Medical Association through local societies and thus the issue between the State Society and the State Association is being forced. Schemes are on foot to swing bodily the smaller county societies into the new organization. The most insidious flattery in the way of personal invitations to read papers at Association meetings and even the relative convenience of travel to New York City instead of Albany and in October instead of January are brought to bear as arguments. It is even stated that the Association has now secured full legal equality with the Society—a statement which is not borne out by fact, although the Association has, by vigorous lobbying, secured more than the usual privileges of private, incorporated societies.

It is bad enough, in this country to destroy anything, even an old house, that has begun to attain respectable antiquity, but, in the present instance, there is a far more practical reason for respecting the ninety-five years of the Medical Society of the State of New York. This Society is a marvelous example of the influence and dignity of the medical profession of a century ago and of the wisdom and foresight of our early legislators. It is the precedent, for the whole country—and for not a few older nations—for establishing the medical profession as a responsible part of the machinery of government. The American Medical Association is, in comparison, a purely informal gathering and even the *Pharmacopœia* has no legal status other than the weight of common acceptance. Every State that has accomplished anything in the way of regulation of medical practice and medical education has, directly or indirectly, based its argument to the people and their representatives, on the Medical Society of the State of New York. The time is not far distant when it will be almost imperative to secure something of the nature of a National medical board, at least in supervising the medical affairs of our new possessions. Already, the weakness of the bond of purely voluntary support of National organizations is being felt and admitted. Is it wise for a minority of the medical profession, a minority whom, personally and scientifically, we must consider with respect, to attack the earliest and most perfect example of State medicine that we possess?

A. L. Benedict, M.D.

Buffalo, March 1, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, February 23, 1901.

EXTRAORDINARY FRAUD OF A MEDICAL STUDENT—OBTAINING HIS OWN DEATH-CERTIFICATE—THE OUTBREAK OF ARSENIC POISONING FROM BEER-DRINKING—HEAVY DAMAGES AWARDED AGAINST THE MANUFACTURERS OF THE CONTAMINATED SUGAR—THE DRINK QUESTION—THE SOUTH AFRICAN HOSPITALS COMMISSION—SEVERE CRITICISM BY MR. BURDETT-COUTTS—AN EQUIVOCAL REPORT—RESPONSIBILITY NOT FIXED—WANT OF POWERS IN THE TAKING OF EVIDENCE—REFUSAL OF EVIDENCE BY THE COMMISSION—ANALYSIS OF THE EVIDENCE—A MAJORITY OF THE OFFICIAL WITNESSES IN FAVOR OF THE ARRANGEMENTS BUT THE INDEPENDENT WITNESSES WERE AGAINST THEM.

"I am the dead body," said Mr. William Browning, described as a Dublin medical student, when arrested on a most extraordinary charge of fraudulently obtaining a death certificate. He was living in lodgings in London and complained of serious illness, took to his bed, and sent a note to a doctor asking to be attended. He described symptoms pointing to Bright's disease. His temperature was high and there seemed no doubt that he was seriously ill. The doctor attended and sent medicine regularly. One evening the patient gave out that he was much worse and had sent for his brother. On the following morning he shaved off his moustache made other alterations in his appearance and proceeded to the doctor's office where he asked for a certificate of "his brother's" death. In answer to the usual questions he said he was present at the death and described the manner in which his brother had died, the details being precisely those which would be expected in Bright's disease. As the nearest relative he was therefore given the certificate. The doctor at the time noticed the close resemblance which the man bore to his alleged brother. So far all went well, but as the doctor made it a custom to see the dead bodies of his patients he proceeded to the house. The room was closed, but after some delay a key was found and he effected an entrance. The room was in darkness, but on the bed he could see the dim outlines of what appeared to be a corpse. The head was wrapped in a pillow-case, which struck the doctor as strange. On pulling the covering he found that there was no head at all! Then, on turning back the sheet he found that the "body" was composed of a couple of blankets. The doctor at once summoned a policeman. On searching the prisoner's box a life policy for $1,000 was found. He alleged that his sole motive was to make his people believe that he was dead.

Messrs. Bostock of Liverpool who supplied the sugar contaminated with arsenic to about 500 breweries in the North of England and were thus the sole cause of the epidemic of arsenical neuritis have been mulcted in heavy damages by one firm, which has received £1,980 for loss of beer which had to be destroyed. Another fatality from arsenical neuritis has occurred. A man, aged fifty-three years, was in the habit of drinking from two to three pints of beer daily up to the time of the arsenic scare, but since then had not touched any. After ailing for four months he became an out-patient at the Manchester Royal Infirmary. He was admitted as an in-patient on January 9th and improved until February 4th, when he sank rapidly and died of heart-failure on the following morning. The necropsy showed that the case was distinctly one of arsenical poisoning. Two other cases of arsenical poisoning have also been the subjects of inquests, with like result.

The drink question continues to trouble medical authorities not a little. The *Lancet*, in an article on the drinking habits of the nation, points out that since the days of Todd—a generation ago—no medical leader has sanctioned the reckless use of alcohol. In an address recently delivered Dr. Carter of Liverpool points out that while the mortality from almost every disease has fallen that from alcoholism is an exception. The deaths have risen from 45 per 1,000,000 of those living in 1878 to 77 per 1,000,000 in 1897. Dr. Carter is impatient with such matters and calls for "legislative or other action."

Mr. Burdett-Coutts, whose now famous letters to the *Times* were the cause of the appointment of the South African Hospitals Commission, has criticised the methods and findings of that body at great length in the daily press. He claims that public opinion has expressed itself very generally to the effect that the report practically justifies all his contentions. But, because he does not find the necessity for that root-and-branch reform for which he has striven made sufficiently clear by the conclusions and recommendations of the Commission, he once more has recourse to the press. The governing defect of the report according to him is that it is weak, inconclusive and equivocal. While it affords confirmation of every charge he has made, it can at the same time be construed into a vindication of everything that has occurred and of every person, authority, and department. In hardly a single case is the responsibility for defects pushed home to its true cause, nor are the widespread and injurious results adequately described. The first essentials to real reform are therefore not supplied. But whenever responsibility can be deprived of a particular incidence, then the Commission treats the matter with some decision. Thus, the undermanning of the Army Medical Corps for which both political parties are responsible is brought into special prominence. When the question of responsibility grows "warmer," as in the case of hospital provision, the delicacy of touch becomes obvious. The crucial test of provision is that there should be hospitals other than those on the march sufficient to accommodate 10 per cent. of the troops. This is a lesson taught by every war.

On February 27th for 100,000 men only 3 per cent. accommodation was provided. But the Report is silent on this point.

The method of taking evidence Mr. Burdett-Coutts strongly criticises. The Commission had no power to compel the attendance of witnesses or the production of documents, or to take evidence on oath. The sense of discipline and the fear of the consequence must have been a great deterrent to official witnesses giving evidence against their superiors. The Commission themselves say, "Our private soldiers are very slow in making complaints." The vast majority of the official witnesses gave evidence in favor of the medical arrangements, but the majority of the independent witnesses, naturally a small section in South Africa, gave evidence against the arrangements. Again out of 75,000 patients treated only 174 were examined—a very insufficient number. The total number of witnesses examined was 462, of which 177 were official. No patient who was in the "famous" hospital of Bloemfontein appears to have been examined, though at least 1,000 men must have passed through it. Of the patients examined only 20 were officers, yet Mr. Burdett-Coutts was denounced as insulting the British Army because he declared in the House of Commons that officers would not come forward. Of the 154 men examined the evidence of 74 was taken at a single afternoon on the occasion of a "state visit" to Wetley. From a great deal of experience in taking evidence on this subject Mr. Coutts is satisfied that such a hurried method of dealing with more or less reluctant witnesses is ineffectual. He found in taking evidence on this subject that even with the aid of a shorthand writer it was hardly possible to get a detailed statement in less than an hour. But in spite of all the deterrent circumstances 47 of the 174 witnesses gave evidence against the arrangements. More than this, the Commission actually refused evidence. Immediately on its return from South Africa Mr. Coutts wrote to the president stating that witnesses who had made statements to him pertinent to the inquiry were willing to go before the Commission. But the president replied that they had decided to hear no more evidence. Now, whether an unprejudiced reader will be convinced or not by the preceding criticisms of Mr. Burdett-Coutts, who is an exceedingly able advocate, making the most of his case, I cannot see how two opinions can exist on this extraordinary refusal of the president—a refusal which is rendered all the more flagrant by the fact that Mr. Coutts was the real protagonist of the struggle and that the Commission was largely in the hands of the other side and that the president had asked him specifically more than once to suggest witnesses. His witnesses consisted chiefly of Colonials, yoemen, volunteers and reservists, who were taking their discharge. They wrote to Mr. Coutts voluntarily. None of them bore any suspicion of malingering or "grousing." They scorned to complain of hardships in the field and unavoidable privations. They confined themselves to faults the remedy for which they could see with their own eyes. When lying side by side in hospital with the regulars the latter had constantly said to them, "Mind you speak up for us when you go home. Tell about these things. It won't hurt you. You know we daren't."

Analysis of the evidence given before the Commission gives the following results: A, *Official,* 1 field marshal, 1 chief of staff, 1 press censor, all in favor of the arrangements; 8 generals, 4 colonels, 1 major, 3 captains, 1 lieutenant, all for, except 3 moderate; army chaplains, 14 for, 4 moderate against. Including transport, ordnance and other officials, out of a total of 56 there were 7 against. In the Army Medical Corps 10 out of 121 officials were against the arrangements. B. *Independent,* civilian doctors in military hospitals, 18 for, 11 moderate, 23 against; civilian doctors in private hospitals, 6 for, 5 against; local clergy other than army chaplains, 6 for, 5 against; civilians (miscellaneous), 5 for, 9 against; lady visitors, 5 for, 9 against. Thus, out of 105 independent witnesses, 55 were against. So much for Mr. Coutts' general criticisms of the methods of the Commission. In my next letter I will deal with a further publication of his in which he comes to close quarters with the evidence.

PES PLANUS—OVARIAN DERMOID CYSTS—RETENTIO PLACENTÆ CORNUALIS—MANUAL EXTRACTION OF THE PLACENTA—RACHITIS IN ANIMALS—GASTRIC ULCER.

Petersen, at the Physiologischer Verein in Kiel, June 25, 1900, in a paper on flatfoot stated the generally-familiar anatomical, physiological and mechanical considerations of the matter and then proceeded to an elucidation of the terms of function. So good an authority as Henke does not mention *pronation,* while others call it at one time *pronation* and at another *abduction.* Uniformity in nomenclature is easily attainable if one imagines the body in the dorsal decubitus position, with the feet bent downward into the horizontal position upon the table till the line of the sole is parallel with the long axis of the lower extremity. In this manner the foot will be in the same relation to the leg as the hand is to the forearm. Starting with the foot in this position *pronation* and *supination* will be any turning of the foot about the long axis of the limb precisely as in the case of the hand, and abduction and adduction will be respectively movement in the sagittal plane of the limb from and toward the midline of the lower as with the hand in the upper extremity. The acknowledgment of such universal distinctions will, of course, be of greatest service in the line of accuracy. The best definition of this common condition is probably given by

Henke in these terms: Pes planus is pes flexus, reflexus, abductus and later may be added pronatus. First, as to pes flexus: The flexion occurs in the upper joint (*talocrural or tibiotarsal joint*), but usually remains within physiological limits. The head of the astragalus is turned backward and the tuberosity of the os calcis is raised. Second, as to pes reflexus: The flexion forces both the astragalus and the calcaneum backward and slightly or tends slightly to raise the point of the foot from the ground. Reflexion then occurs in the mediotarsal joint and when physiological limits are exceeded a subluxation occurs. Then the arch of the foot is flattened and slightly sunken. Third, as to pes pronatus: The twisting of the foot in this element of the lesion is mainly in the lower ankle-joint, especially the talocalcaneal articulation. The os calcis turns about, so that its outer side looks more and more upward and, finally, in the last degree of bad cases, makes an articulation with the point of the external malleolus. The whole calcaneal axis is displaced outward beyond the center of gravity of the leg. The height of the arch of the foot touches the ground and the foot has become deformed. Even here at this stage all the physiological limits of motion are exceeded. Pes abductus, the fourth element, presents a displacement outward of the foot so that the anteroposterior axis of the foot is broken into an angle. The apex of this angle is at the mediotarsal joint and is formed by the head of the astragalus which has sunken inward and downward. To this actual abduction must be added a certain degree of pronation. Concerning the mechanical cause of flatfoot, the speaker said that the ordinary manner of walking with the toes turned outward is a highly favorable condition for it, because in this manner the outer border of the foot first reaches the ground and first receives the weight of the body, while the inner remains lax. This uneven distribution of the body weight has a large causative influence upon the succeeding stages of the finally complete lesion.

Habs, at the Medicinische Gesellschaft zu Magdeburg, November 8, 1900, presented a specimen of ovarian dermoid cyst obtained by operation the contents of which were the following parts of a face: The upper eyelid was fully developed and the lower but partially so. Each had lashes and the upper a brow. Behind them was a sac representing the eyeball. A considerable part of the forehead, with scalp and hair, was present and the supporting base of it all was a fragment of the frontal bone.

Thorn discussed the important topic of retention of the placenta in the horns of the uterus. Just as the implantation of the fertilized ovum over the internal os may lead to abortion, its lodgment in the uterine cornua is filled with danger. Foremost is the fact that when abortions take place under these conditions, the chorion is very apt to be retained. Out of the last 100 abortions carefully observed eleven suffered from cornual retention of the chorion, to which may be added two recent cases. The anatomical form of the uterus is a potent factor in causing it by an undue development of the horns. Displacements are also important, especially retroversions. Of the eleven cases mentioned the right cornu was five times and the left cornu six times the size of the chorion. The treatment was for the most part curetting, repeated in some cases as often as three times, but without result. Such retentions of the chorion are much more important in practice than the text-books state. If the bleeding and other symptoms persist after the curetting, it is best not to repeat it often or too vigorously, lest the uterus be perforated. Only an adept can expect to clean out successfully a deep uterine horn. It is far better for every one to dilate the cervix and explore with the fingers in order to know just what the conditions are. Such dilatation had best not be done with force, but with laminaria or some of the gradual means. Under antiseptic precautions they are safe and are free from any risk of lacerating or rupturing the soft uterine tissues. The technic of a digital evacuation of the uterus is as follows: When the cervix is with difficulty penetrable, it is well to seize its anterior lip with a volcellum, so as to draw it well over the fingers upon the hand and secure it there. In this manner a uterus with a long neck and a large, soft body can be more easily explored and treated. Digital emptying of the womb should be oftener resorted to, while its details are more difficult than those of mere curetting it is *per se* far less hazardous. At the present time it is probable than manual extraction is practised far oftener than necessary. In consequence of this and very likely still more of faulty technic it is responsible for the majority of puerperal fever cases. In his own consulting practice he finds it is the cause of three-quarters of all the troublesome postpartum complications and sequelæ. He therefore utters the dictum that present methods may be greatly improved. Olshausen recommends rubber gloves in cases which are intrinsically septic and when the opportunities for sterilizing the hands are imperfect or the hands have, in spite of care, probably been in contact with septic material. Certainly rubber gloves in more general use will be of service. To the experienced hand there are two moments during the extraction, which are trying and lead to imperfect work. First is that of an alarming hemorrhage which almost always follows the introduction of the hand. Second is the unfamiliarity of the hand to the feeling of the postpartum uterine cavity. The undue haste on account of the first factor and the incomplete work of each cause only partial

extraction to result, or the infection of the placental site by a reintroduction of the hand through the externalia. Vaginal extirpations have taught us that uterine hemorrhage can be lessened by drawing the organ downward until the external os corresponds with the introitus vaginæ, thus causing a strong kinking of the uterine blood-vessels, with consequent decrease in the flow of blood. The postpartum uterus similarly permits itself to be drawn far down into the vagina by means of a volcellum attached to the anterior lip of the cervix. If one desires to be exceedingly careful one has only to insert a speculum in addition to have all in full view. The addition of a pair of wide short-blade specula to every complete obstetrical set is now an absolute necessity. In an emergency the blades of the forceps can be used as retractors. Another efficient substitute is to seize the anterior and posterior lips of the cervix with strong volcella and, drawing the uterus strongly down, consign each to an assistant for holding. The gloved left hand now follows the umbilical cord into the uterine cavity and cleans it out, while the fundus is supported from above by the right hand.

Hansemann at the Berliner medicinische Gesellschaft, December 12, 1900, read a contribution to the study of rachitis, concerned chiefly with observations of the disease among monkeys and other animals confined at the museums. Monkeys in confinement in almost any climate are very apt to develop rachitis in varying degrees, often very extreme. The bearing of simply unnatural conditions in their confinement is of manifest weight and very suggestive of the real cause of the disease among children. The absence of ordinary chloride of sodium from the food has been claimed to be a potent cause too. This the writer has not yet been able to verify and prove beyond all doubt, but it probably has considerable influence on the disease.

W. Körte, at the Verein für innere Medicin in Berlin, December 17, 1900, discussed the subject of gastric ulcer and its relation to surgery. Primarily gastric ulcer belongs to the realm of internal medicine and only its sequelæ or complications come under the care of the surgeon. Even in these it is the rule that first of all the various means of medical treatment shall first have been exhausted. Benign cicatrical stenosis is the first good indication for surgical interference. In carcinoma the difficulty is that a diagnosis is established too late to permit of any good result. In the benign scar-tissue contractions the treatment is directed not to the ulcer itself, but to the result of it. The open ulcer will be amenable to surgery when its site can be fixed at the pylorus and all means for internal treatment have failed. Hemorrhage often constitutes an urgent indication, but surgery is then both a last and a doubtful resort. What shall universally be the deciding factors in hemorrhage determining for operation cannot be fixed. One must distinguish one case from another on its own merits. The dangers of gastric surgery are considerable and must never be lost to view. They comprise chifly the power of resistance on the part of the patient, which no skilful practitioner will permit to become too depreciated, and the condition of his other organs, notably the respiratory tract. Pneumonia in these cases appears to be rather common and its dangers are great. The size and depth of the ulcer are beyond the means of diagnosis until the abdomen is opened. The danger of infection of the peritoneum has within the power of human beings been reduced to a very small element. Sicknesses which follow the operation are various. The most important and fatal is pneumonia. Why it should occur is difficult to say. One theory states that the painfulness of the abdominal wound leads to shallow respiration and this faulty function favors the pneumonia. There does not appear to be any direct way of avoiding it and it is to be expected with a preceding bronchitis. In his own practice he has had twenty male and seventeen female patients submit to operation. The greater number of males is due in part to the fact that they must submit to the requirements of work and hence regard the operation as a shorter treatment and that, as a rule, men submit less patiently than do women to long and laborious courses of treatment. The smaller number of women is against the common experience that gastric ulcer is more common among them than among men. The age limits varied between sixteen and sixty-one. Among the younger series, females again predominated. The extreme duration of the preliminary sickness was thirty years; three less than one year and one stated it at five weeks. The usual symptoms were emaciation, vomiting and pain. In thirty-one patients dilatation coexisted with the stenosis. A few time the stenosis was situated not at the pylorus itself, but at the pars prepylorica. Excess of hydrochloric acid was present in twenty-four cases. The differential diagnosis from cancer is not always possible to make, not even at the operation unless a microscopical examination can be had. For conditions due to the ulcer, independent of stenosis, he had operated twice. Of the three operations, resection, pyloroplasty and gastro-enterostomy, the last is to be considered the normal in the majority of cases. Resection is to be thought of only when carcinoma is suspected. He has done five resections with one death, twenty-eight gastro-enterostomies with twenty-one recoveries. Two of those who died were lost by secondary hemorrhage from the ulcer. Hence the anastomosis cannot be regarded as curative of the bleeding of these sores. Before he adopted the retrocolic anas-

tomosis he had two cases of *circulus viciosus*, but since then he has had nineteen consecutive cases without it. There is one accident in these cases which he has observed a single time. The gastric ulcer may recur and perforate or may extent into the jejunum and then perforate. His patient had remained well three years and died of peritonitis due to a perforation of a peptic ulcer through the jejunum. The other ultimate results were permanent, as the patients without exception regarded themselves as healthy mortals. Pyloroplasty (Mikulicz-Heinecke) gives devious results. The Murphy button is not advisable. For the cure of actual bleeding, operation is very difficult to perform and uncertain in its results. It should be a final resort in the grave cases.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held January 18, 1901.

George R. Elliott, M.D., Chairman.

Deformity of Adolescence.—Dr. Homer Gibney presented a girl, aged seventeen years, tall, with a round back or posterior curve of adolescence of which he exhibited a tracing. He had applied the plaster jacket she now wore, only a few hours before, by placing her in the recumbent position, the body resting upon two uprights—one under the pelvis and the other under the point of greatest prominence of the back. Her head and shoulders were allowed to sag backward and downward. The position maintained, which caused the patient some suffering, was a marked overcorrection. Another jacket would be applied later. The patient did not bear the operation well, on account of cardiac complication.

Dr. Henry Ling Taylor said he had not understood what diagnosis had been made, but the girl seemed unusually tall for the age assigned, and asked if the possibility of gigantism had been considered, as a marked round back was common in such conditions.

Dr. Royal Whitman said he was familiar with the history of the patient. She had some cardiac disease, was rickety, overgrown and badly nourished. He considered her condition merely the round spine of adolescence partly due to her height and heart weakness, and called attention to the fact that the patient showed lack of ordinary intelligence.

Dr. W. R. Townsend said that he had put up a case of *spondylose rhizomelique* last week in a much straightened position, followed by a feeling of relief to the patient.

Dr. Taylor remarked that Kietley had described anterior crutches to hold the shoulders back, which would seem to answer the purpose of epaulettes as used in this jacket, without their disadvantages.

Epicondylar Fracture of the Elbow.—Dr. Homer Gibney presented a small boy who had sustained a fracture of the elbow three months previously. The fracture was above the condyle. When the patient presented himself at the Hospital the elbow was fixed at an angle of 105 degrees with but little movement. The joint was cut down upon by Dr. V. P. Gibney and the detached fragment sutured into place.

Dr. V. P. Gibney said the epicondyle and nearly the entire condyle had been displaced, interfering with motion. He had cut down upon the joint and separated it with an osteotome, cleaned off the site of the fragment and pushed it down suturing with kangaroo tendon; he then put the arm in a straight position, left it for four or five weeks and then allowed active motion. Passive motion was not employed.

Dr. T. Halsted Meyers commented upon the excellent result and remarked that children were often allowed to go on with fracture at the elbow united in poor position in the belief that they would outgrow the disability in great degree which was true, but it was better to correct the deformity entirely, even resorting to open operation when necessary. He called attention to Dr. Lloyd's excellent reports.

Coxa Vera.—Dr. Townsend presented a boy, aged 14 years, with the history that three years ago, without apparent cause, he began to limp and noticed that one leg was a little shorter than the other. The condition increased and he has had some pain. There was one inch of actual shortening. Radiographs were shown. He diagnosticated coxa vera of the ordinary type. He said there were two points to note; one, good flexion and extension with little adduction; the other, the smaller size of the limb. He showed another skiagraph of a patient in whom he had made the diagnosis sometime ago of coxa vera. In this case under observation for three years there had been a progressive shortening of about ⅛ to ¼ inch each year, now amounting to ¾ inch.

Dr. Whitman called attention to the importance of the limitation of motion, that although the patient still retained ten per cent. of abduction, there was an apparent shortening of two inches. This shortening and consequent disability was due to the limitation of abduction. This deformity might be overcome, after preliminary stretching of the contracted muscles, by a cuneiform osteotomy at the base of the trochanter which would reestablish the angle of the neck and thus relieve the strain upon it. He advised this operation in Dr. Townsend's patient, though the best results were to be looked for in younger patients, or at an earlier stage of the deformity.

Dr. Elliott asked Dr. Whitman how large a wedge of bone he would remove.

Dr. Whitman suggested cutting a paper model of the bone as shown in the skiagraph, and measuring on that the size of wedge to be cut out; he thought one with a base of ¾ of an inch would be sufficient in the case under discussion. The actual increase in length of the limb would be slight, possibly ½ inch; the important point was that there would be no apparent shortening, because there would be complete relief of the limitation of motion which caused the apparent shortening.

Dr. Townsend said he had performed the operation referred to by Dr. Whitman in two cases with good results and saw no reason why it should not be done in this case. In one patient, however, a little girl aged 7 years, who had slight coxa vera, he had applied a traction splint and did not see in this particular case why it was not as good as the osteotomy advised by Dr. Whitman. He thought apparatus worn for a few years would give good results in the mild cases.

Dr. Meyers agreed with Dr. Townsend that it would be better in the beginning of these cases to use some sort of supporting apparatus that would not need bandage or plaster, thus avoiding pressure atrophy. He thought the Campbell brace especially adapted for such cases. It removed part or all of the body weight and was inconspicuous.

Dr. Taylor said that this brace reminded him of the Dow's brace which was valuable when it was desirable to use a perineal crutch and allow motion at the knee. He cited cases which had done well under the use of the hip splint, but could not give final results as the patients had not returned after treatment was discontinued. He had recently seen a case of coxa vera in consultation when four out of six surgeons consulted were in favor of the splint treatment.

Dr. Whitman did not favor the use of apparatus as a routine treatment, believing that after its discontinuance the distortion was likely to increase and the nutrition of the parts was likely to be lessened rather than increased by the use of braces. He had been disappointed in the final effect in cases in which apparatus had been used. Finally, braces could not rectify the deformity, at best would but relieve the symptoms and check progress. His operative results had been satisfactory. The patients after operation did not limp. Nearly all of his operative cases were between the ages of six and ten years.

Dr. Louis A. Weigel, of Rochester, N. Y., thought apparatus might be used to advantage in the earlier stages of coxa vera for the removal of superincumbent weight which is an etiological factor. He believed the difference in size of the femora as shown in the radiographs was due to a true atrophy or arrest of development. If coxa vera is due to defective nutrition, development of the affected side would be retarded.

Fracture of the Neck of the Femur.—Dr. Townsend presented a man, nineteen years of age, who in December, 1899, fell a distance of 40 feet, striking on his hip. A diagnosis of contusion was made at the hospital to which he was taken where he remained in bed six weeks, at end of which time he could not walk except with the aid of crutches. He came to Hospital for Ruptured and Crippled in April, 1900, and a diagnosis of fracture of the neck of the femur was made. There was one inch of shortening, inversion of foot, crepitation at site of fracture when movements were made. Extreme pain and inability to bear weight on the limb or lift it from table when lying on his back. A long traction hip brace and a high shoe were applied and worn for six months. The man can now walk with little or no pain, and when lying on his back can raise his leg nearly as well as on the sound side. There is one inch of shortening, no crepitation at hip and all motions are possible without pain. Dr. Townsend thought traumatic coxa vera could be applied to this case.

Dr. Meyers thought the case very encouraging. He had presented a similar case some time ago in which bony union had been secured after four months of non-union. In all cases of fracture of the neck of the femur, an earnest attempt to get bony union should be made. In recent cases even in old people with proper splints one would succeed many times. In old people in whom there had been fracture without real immobilization for many months, the case was not hopeless under proper treatment.

Congenital Absence of Bone.—Dr. Weigel also presented a series of radiographs showing congenital absence of bones in members of the same family. In the five extremities shown, some bone of the hand or arm was absent. In one case, there was a rudimentary humerus, an imperfect thumb and three fingers. The mother had no thumb and gave a history of having borne twelve children, four of whom were deformed. The mother attributed her own deficiency to maternal impression, stating that her mother while pregnant was shocked by seeing a man at her house without a thumb.

Osteomyelitis and Tuberculosis.—Dr. Weigel exhibited another radiograph of a case of extensive osteomyelitis involving the whole of the tibia on one side. The patient had been treated for articular rheumatism. He thought it possible in most cases to make the differential diagnosis between marked suppuration and thickening or eburnation. When there is pus formation, he stated that it is difficult to get a clear definition of bone structure in a radiograph on account of the osteoporotic condition usually present.

Dr. Weigel also exhibited a radiograph of a tuberculous focus in a child's foot, together

with another radiograph taken two months later, showing the repairative process already well under way. This patient was treated by fixation and rest, any radical surgical interference being contra-indicated.

Dr. Townsend asked for a differential diagnosis between sarcoma of bone and osteomyelitis.

Dr. Weigel said that such a differential X-ray diagnosis might be difficult to make without an opportunity of comparing a series of cases.

Dr. Elliott showed a skiagraph of congenital dislocation of the hip which was taken after only fifteen seconds of exposure. The shortness of time exposure was important. With restless children long exposure was often impossible without an anesthetic.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held February 12, 1901.

The President, Robert F. Weir, M.D., in the Chair.

Menorrhagia in Young Girls.—Dr. P. F. Mundé was to have spoken on Uterine Hemorrhage: Its Causes and Significance, but was prevented by illness and his place was taken by Dr. W. Gill Wylie. Dr. Wylie thought too little attention was given to the proper establishment of menstruation, which is apt to be interfered with by study and, in the better classes of society, by social distractions. The hygienic care of young girls should be quite different from that of boys, and is of much greater importance. It is essential that the girl should be in complete health. If she is weak and anemic she ought not to menstruate at all. In such conditions of the system, however, the uterus is the easy prey of disease. The endometrium is apt to become abnormal. Fungous growths are developed, and, in consequence, the menstrual flow is excessive. It is too often lost sight of that in an enfeebled system the amount of menstruation ought to be less than in the case of a healthy girl.

Metrorrhagia Due to Neoplasms.—The two great varieties of neoplasms causing hemorrhage are carcinoma and fibroids. Neoplasms are most important after the age of forty. It has been the too-generally-accepted opinion that the menopause alone will cause abnormal flow. The fact is that the flow is not excessive except when disease is present, and the form of the disease is especially likely to be cancer. It should not be forgotten, too, that when taken in hand early cancer can be more successfully treated in the uterus than in any other part of the body, on account of the freedom from glandular complications. Unfortunately, the opportunity for this is too often lost, either because the patient, regarding the hemorrhage as merely incidental to the menopause, does not seek medical advice at all, or, if she does, because the physician is of this opinion also.

Metrorrhagia Due to Inflammatory Processes Within the Pelvis.—Dr. E. B. Cragin said that the three factors concerned are the endometrium, the muscle-wall of the uterus, and the blood-vessels of the organ. Acute endometritis is usually of bacterial origin, while chronic endometritis, as a rule, follows upon acute congestion and is not the result of acute endometritis. As to the muscle-wall, if the contractions are normal and unimpeded, the circulation of the uterus and the loss of blood from the organ are normal. If not, these are increased. The two conditions which most commonly interfere are (1) tumors of the uterine wall, and (2) chronic interstitial inflammation, causing atrophy of the muscle-wall. In acute endometritis rest is the most essential thing. In chronic, curettage is usually the best treatment. In cases in which repeated curetting fails to check the hemorrhage, the removal of the uterus may be justifiable.

Metrorrhagia During the Puerperal Process.— Dr. J. Clifton Edgar spoke first of the causes of antepartum hemorrhage. In addition to the more common ones of threatened abortion, placenta previa, extra-uterine pregnancy, etc., he said it was necessary to take into consideration the possibility of bleeding from the urethra and from hemorrhoids. Also the possibility of menstruation continuing into pregnancy, and even, in exceptional instances, throughout the course of pregnancy. Hemorrhage due to implantation of the placenta in the lower segment of the uterus is more common than is generally thought. Placenta previa is not supposed to occur before the thirty-second week of gestation; but Dr. Edgar said he had in his possession specimens from a case at the sixteenth week. Intrapartum hemorrhage may occur in both the first and second stages of labor. In the third stage the most important cause of hemorrhage is uterine inertia. It may also be caused by lacerations of the cervix, perineum, etc., and partial or complete inversion is also a rare cause. Secondary postpartum hemorrhage takes place in from six hours to six weeks after the completion of labor, and generally depends on causes operating at the time of labor. It may be due to anything which interferes with the progress of subinvolution, such as incomplete third stage, retention of membranes or blood-clots, displacements, and too early sexual intercourse.

Uterine Hemorrhages Due to Organic Diseases in Other Organs and to Constitutional Disturbances.—Dr. Andrew H. Smith said that hemorrhage due to diseases in other organs was almost always the result of ob-

structed circulation, as, for example, in affections of the heart and liver. His observation led him to think that women suffering from hemorrhoids were liable to excessive menstrual flow. Abdominal tumors also frequently press upon the veins to such an extent as to cause uterine hemorrhage. In all these cases the cause of hemorrhage was principally mechanical. In speaking of constitutional causes he referred to syphilis as liable to produce a fragility of the walls of the blood-vessels and to changes in the blood itself which tend to promote adhesive leakage in the vessels. The thinness of the blood, as it is commonly spoken of, in anemia, for instance, may result in uterine hemorrhage. Later on, when the anemia has reached a more extreme point, amenorrhea is apt to be caused. In *purpura hæmorrhagica,* where there is an abnormal condition of the blood and perhaps also of the vessels, it is not uncommon to find an undue flow from the uterus. Other causes mentioned were, prolonged lactation, extreme fatigue, scurvy, scrofula and the exanthemata. In typhoid fever there is a special form of hemorrhage, to which the name of uterine epistaxis has been given.

Treatment of Placenta Previa.—Dr. E. A. Ayers said that in many respects this was the most difficult condition to deal with in gestation. The problem was to secure expeditious dilatation, with as little hemorrhage as possible, and the delivery of a living child if practicable. Of the various methods of dilatation he had found the use of Barnes' bag the most satisfactory. Dilatation having been accomplished, the child is to be promptly delivered by podalic version.

Menorrhagia Without Pelvic or Uterine Disease.—Dr. J. R. Nilson said that in cases of this kind the object should be to promote reaction and assist what he termed the resistive forces. This could best be accomplished plished by judicious packing and systemic treatment.

Menorrhagia Due to Fragments of Retained Decidua.—In another class of cases, where there was some tenderness about the uterus, he always used the curette; and here packing should never be resorted to except, perhaps, as a temporary expedient. The whole cavity should by no means be curetted, but simply the rough spot caused by the fragments, which were almost always located in one of the cornua. The sharp curette was the proper instrument to employ, and it should be very lightly passed over the surface until the rough spot was encountered.

Types of Menstruation.—Dr. A. Brothers said that the practitioner sometimes saw various types referred to, such as the two-weekly type, the three-weekly type, the four-weekly type, etc. There was, however, but one normal type, *namely,* the four-weekly one, and when he read of anticipated or delayed periods he knew that there was in reality some underlying pathological condition.

When Tamponing Is Justifiable.—Dr. A. Flint, Jr., said he did not believe the tampon should often be used in ordinary menorrhagia, but there were a few exceptional cases in which the condition seemed to be of the nature of hemophilia and in which its use was attended with the best results. For instance, he had regularly tamponed one woman at each menstrual period for the last five or six years, simply for the purpose of saving her blood. As a result she had gained greatly in weight and had grown strong and healthy.

The Abuse of the Tampon.—Dr. Wylie thought the tampon had been greatly abused, and said he would not resort to it except in such cases as Dr. Flint had referred to. If it is successful in checking the flow, the uterus is apt to become distended and the blood which cannot escape through the cervix is forced out through the *ostia interna,* with the result of causing such evils as cellulitis, local peritonitis and ectopic gestation.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting February 5, 1901.

The President, Joseph Collins, M.D., in the Chair.

Locomotor Ataxia Trained by Fraenkel Method.—Dr. A. Wiener presented this man. He had been under this system of training for about one year, and while ataxia was still present, he had been very greatly improved, and was now able to go about even at night unaided. There had been no other treatment for the tabes.

Sarcoma of the Brain.—Dr. A. Wiener also presented a pathological specimen from a patient, seventeen years of age, who had first come to him about November 1, 1898. There was an absolutely negative history of alcoholism or syphilis. About two years before this time the patient had suffered from a severe fright, and almost immediately thereafter had had a severe convulsion. Nothing further had been noticed until the summer of 1898 when she had suddenly developed a difficulty of speech, with right facial palsy. She had frequently suffered from bad headaches for three months previously. On coming under observation there had been excruciating pain over the occipital region, complete deafness in the right ear and a bulging of the tympanic membrane. The right sternomastoid muscle had been in a state of constant contraction, and there had been a double optic neuritis, most marked on the right side. The voice was hoarse. Neither the upper nor the lower extremities had suffered any loss of power. There was no swaying when the eyes were closed, nor was there any bladder trouble. Her temperature was

100° F. The seventh, eight, ninth, tenth, eleventh and twelfth nerves were affected on the right side, and the sixth nerve on the other side. On November 8th, a slight ptosis had been noticed, and the twelfth-nerve palsy had become more marked. On November 28th there had been vomiting, vertigo and an increase in the ptosis of the left eye. On December 8th there had been complete third-nerve palsy on the left side, and the headache had been very severe. Having diagnosticated a tumor of the brain the patient had been sent to the Mt. Sinai Hospital. A mass had developed behind the ear, and on aspirating this, it had been found that the case was one of congenital sarcoma. On January 11, 1899, the third palsy had entirely disappeared on the left side, and the swelling behind the ear had grown larger. On January 21st, the patient had suddenly become confused and blind in both eyes. In April it had been decided to open the mass to relieve the pain. By June 30th the patient had been up and around again. In October there had been a complete brachial plexus palsy on the right side. The tumor had kept on growing until almost the size of the patient's head. The patient had died in February 2, 1901, and an autopsy had been performed. The whole tumor had been found below and outside of the brain. In front was a large giant-cell sarcoma which had completely destroyed the sphenoid bone. At the back the tumor had destroyed the occipital bone. The brain was exhibited, and it showed that only the pons had suffered pressure. The tumor had apparently started in the mastoid portion of the temporal bone.

Tendon Transplantation for Deformity of the Hand.—Dr. W. R. Townsend presented a case of this kind, which had been exhibited to the Society about one year ago. It was a case of infantile cerebral palsy. Instruments had been used at the time of birth, but no damage had apparently been done to the exterior of the skull. He had never been able to use the right hand, and it was a typical "claw hand" when the boy came under observation at the age of fifteen years. On December 21, 1899, an incision had been made over the wrist, exposing the tendons. The flexor carpi radialis, the flexor carpi ulnaris and the palmaris longus were divided just above the annular ligament. The hand was then turned over and an incision made on the dorsum of the wrist, and the extensor communis digitorum exposed. A dissection having been made through the interosseous space, the extensor tendon was pushed through, and, being too long, was doubled upon itself. It was then attached to the tendons previously mentioned. The union of the tendons had been satisfactory and permanent. The tendons had not shown any tendency to unite to the surrounding tissues. He was now able to write fairly well whereas formerly he could not even grasp a pen.

Dr. B. Sachs said that he had been deeply interested in this subject, and it was certainly the best procedure that had been suggested for these cases of contracture whether of spinal or cerebral origin. The problem was to split the tendon of the overacting muscles and unite them to the tendons of the underacting muscles, and so restore the equilibrium of power. It had been found prudent not to allow the patient to exercise much or to use electricity until the tendinous union had become very firm. It was unfortunate that this boy was not able to extend his fingers, yet he had secured good extension of the wrist. In spite of the tendon transplantation the boy experienced no difficulty in producing flexion when he desired to do so.

Dr. Schlapp remarked that it seemed to him that the boy's hand was decidedly larger now than when he had seen the case a few months ago.

Neurotic Skin Affection.—Dr. Creighton presented a young woman, of neurotic temperament, who four years ago had had hysteria and typical attacks of *grand mal*. One year ago she had had the grip followed by pneumonia, and this had been succeeded by headaches, aching spine and numbness in the left side. There were severe contractures in the left arm. A small painful tumor had appeared in the left palm, and had been removed by the family physician under cocaine. It had returned, and had been again removed. A galvanic current of 10 milliamperes had brought out a slight redness on the palm. Three days before menstruation a large red spot had appeared on the back of the forearm, and soon afterward several similar spots had made their appearance on the arm. A few days before the next menstruation these spots had returned, and, in addition, a number of large blotches on the left shoulder and on that side of the neck. The whole side was very hyperesthetic. There was slight narrowing of the visual field, and there was left-sided sweating. The speaker said that the case was very similar to one recently reported from Erb's clinic.

Dr. Joseph Fraenkel asked whether there had been a history of malaria, and whether the case might not be looked upon as one of morphea.

Dr. Creighton replied that there was no history of malaria, and the family physician had stated that the tumor which he had removed grew on the nerve. The microscopical examination had been made at the laboratory of the Presbyterian Hospital, and the report had been that there was a slight round-cell infiltration only, no nerve-degeneration being found. The thyroid gland was not enlarged.

Dr. C. L. Dana said that he had seen cases presenting just this appearance, but entirely free from hysteria.

Dr. W. B. Noyes said that four or five skin lesions were closely associated with nervous

troubles. Herpes zoster, erythema multiforme, Raynaud's disease, all were distinctly related to the nervous system, yet it was very difficult to state the exact relation. It had occurred to him that the element of suggestion regarding the connection with the nerve might be responsible for some of the phenomena present.

Dr. E. D. Fisher said that this could not be properly described as simple hysteria, or as the result of mere suggestion. The eruption was not characteristic of an hysterical state.

Dr. M. G. Schlapp said that these cases had been described before; they had been brought on by suggestion. In this case an injection had been given in the arm, and shortly afterward this dermatitis had first appeared. The eruption was not characteristic of any particular skin lesion, but it closely resembled cases that had been described as hysterical skin manifestations. In typical zoster there was frequently a degeneration of the nerve-fiber itself.

Dr. Sachs said that the case was a very unusual one, and he did not regard it as belonging to the class of hysterical hyperemia. It was certainly a distinct form of skin neurosis. The closest resemblance in the anatomical distribution was to herpes.

Dr. Joseph Collins said that if the girl should develop a pneumonia he would not be willing to call it an hysterical pneumonia; neither was he willing to call this an hysterical skin disease. He was inclined to think it was closely related to morphea.

Dr. Creighton said that a case had been reported very recently in which the gangrenous form had ultimately developed. This case had been described as hysterical. Dr. J. C. Johnston, the dermatologist, had seen this patient and had looked upon the case as hysterical.

Paralysis of the Spinal Accessory.—Dr. Pearce Bailey read this paper. He said that the chief interest of this nerve was surgical. Within the past year two instances had come to his notice of accidental section of the nerve. In most cases the paralysis which results from section was not particularly disabling, but such had not been the case in the instance to which he referred. When the sternomastoid was completely paralyzed the freedom of movement of the head was interfered with, but not totally abolished. In the two cases referred to the disability had been unusually great, and had led him to study more carefully the nerve-supply. It was now regarded as a spinal nerve, pure and simple. The spinal portion of the nerve, represented by the external branch, springs from the upper five segments of the cord. Paralysis of the nerve presents a varying symptomatology according to the site of the lesion. An injury outside of the skull to cause symptoms referable to both branches must be situated directly at the base of the skull. The extracranial lesions of the spinal accessory are confined to the external branch, and are nearly always traumatic. Neuritis in this nerve is rare. A case was cited to illustrate the possible traumatic origin of spinal accessory palsy by injury with a blunt instrument. In two other cases reported the paralysis had been directly the result of operation. In the second case the resulting incapacity had been so great that the right arm had been rendered practically useless for any heavy work. Neurorrhaphy had been performed about six weeks after the operation at which the nerve had been injured, and the ends of the divided nerve had been found separated over one inch. The improvement in motor power had been slow. A reference to literature showed conflicting views regarding the nerve-supply. Dr. Bailey said that the spinal center between the first and fifth cervical segments of the cord was fixed and constant, but occasionally all the axons pass to the muscle by the spinal accessory. Under these circumstances the motor impulses reach the trapezius through the spinal accessory, and hence section of it means total palsy.

Dr. W. M. Leszynsky said that he had seen a patient two months ago who had been operated upon for torticollis. Over one inch of spinal accessory nerve had been removed on the left side without relief, and the function of the muscle had remained perfectly normal. He had seen over an inch of the other spinal accessory nerve removed subsequently, yet the muscle had not been affected at all; hence he had held that it was useless in these cases of spasm to operate upon the spinal accessory nerve.

Dr. J. Arthur Booth said that he had had a case of spasmodic torticollis operated upon by section of the spinal accessory nerve. A little more than one inch had been excised, and the sternomastoid and part of the trapezius had been paralyzed as a result.

BOOK REVIEWS.

The Surgical Treatment of Congenital and Pathological Disfigurements of the Face. Abstract of the Mutter Lectures of the College of Physicians of Philadelphia for 1900. By John B. Roberts, A.M., M.D. The Philadelphia Medical Publishing Co., 1900.

This is a very succinct and suggestive exposition of a subject that has been allowed to remain too much in the hands of the charlatan. The fact that the book is made up from the Mütter Lectures is the best proof of its merit. The additional fact that it consists of abstracts only with the omission of all conventional details is the best proof of how useful it may be to the general practitioner. The subject is treated in thoroughly up-to-date fashion.

Rudiments of Modern Medical Electricity. By S. H. Monell, M.D. Edward R. Pelton, Publisher, New York.

This little manual was prepared on the question-and-answer plan. This makes it necessarily rather fragmentary. It may be advisable to write up the subject in this way for the sake of students, but it ruins the connected treatment of the subject. Considering this disadvantage the little book is well done and comparatively complete. The unfamiliar ideas of electricity are conveyed in a pleasing and always in a plain, accurate and straightforward way.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Surgery, etc. Edited by Henry W. Cattell, M.D. J. B. Lippincott, Philadelphia, 1901.

The present number of "International Clinics" is well up to its usual high standard: The opening article is on the United States Pharmacopœia, by Dr. H. C. Wood of Philadelphia. This gives a very good idea of what the Pharmacopœia is and what it is not, and especially what it should not be, and is opportune, since during the year just passed the United States Pharmacopœial convention obtained a legal status by incorporation in the District of Columbia.

One of the striking articles is a characteristic contribution from Professor Potain of Paris on the Indications and Contra-indications for the Use of Digitalis in Treating Heart-disease. While the present volume was in press Professor Potain passed away. His precious lessons at the Charité in Paris are to be no more. Some of his work, especially such as he put in shape for clinical teaching, will surely live as a heritage for our generation at least. This dictum with regard to digitalis is interesting: "Its action in man and in animals may differ. With our patients it may differ in the healthy man and in the sick one, and even in the single patient it may act differently at different times, according to what the disorder may be. Observation alone is able to supply positive indication." This is the true status of our practical knowledge with regard to the use of digitalis.

There are interesting clinical articles on the Treatment of Chronic Gonorrhea by Alexander Renault of Paris: on Mercury and the Systematic Treatment of Syphilis by Professor A. H Ohmann Dumesnil of St. Louis, and on the Treatment of the Complications of the Syphilitic Chancre by Professor Fournier of Paris. There are also very interesting special articles by Professor Grassi on Mosquitoes and the Prophylaxis of Malaria and on Blastomycetes as the Cause of Cancer by Professor Roncali of the University of Rome. Both these men were largely concerned in making the discoveries in the subjects of which they treat

This is the second successive volume of "International Clinics" of the present series in which a considerable amount of space has been given up to genito-urinary diseases. It would seem that this narrow specialty occupies too much space considering of how little interest the subject is to a great many practitioners. In each of the last two volumes, moreover, the concluding article is a long monograph. In the present number the monograph is on the Morbid Anatomy of Various Diseases and occupies more than 100 pages. This is such a radical departure from the usual custom of the Clinics that it is very noticeable, and is not apt to meet with much favor among old readers.

Diseases of the Heart; Their Diagnosis and Treatment. By Albert Abrams, A.M., M.D. G. P. Engelhard & Co., Chicago, 1900.

This is one of the series of monographs on practical subjects, each of about 150 pages in length, that is being issued by these publishers. This volume is a thoroughly practical little manual. There is in it a tendency to dogmatism that is inevitable, presumably, with text-book methods. The statement, for instance, "As a rule, pulmonary tuberculosis rarely develops in an individual with a valvular heart-lesion," is certainly doubted by good authority.

It is refreshing to find the importance that Dr. Abrams attaches to accidental heart-murmurs. He insists, very wisely, on the fact that heart-murmurs, especially systolic heart-murmurs, very often do not mean an organic heart-lesion.

Dr. Abrams finds a place in his diagnostic category for murmurs of apprehension. He thinks that even diastolic murmurs may be accidental or functional. This is carrying the question of function rather far, especially in the treatment of the subject for students. Diastolic murmurs are almost without exception (if there are really any exceptions) of organic origin. On the whole, the little book is a very suggestive presentation of the cardiology of the day.

Panama and the Sierras. A Doctor's Wander Days, by G. Frank Lydston, M.D. The Riverton Press, Chicago, 1900.

This is a very pleasant, breezy story of a doctor's wanderings during a winter holiday. It is not a connected sketch of continuous travel, but a series of good things as seen through a doctor's eyes. Nearly everywhere one finds the doctor's way of looking at things, and there is a sympathetic view of human nature in varying moods that shows the man of large knowledge and large sympathies with Nature's under side.

The illustrations are reproductions of the doctor's own photographs; the book is full of them and none are introduced merely for the sake of adding to the number. The overworked doctor, who has been long sighing for a rest and whose dreams have brought to him passing thoughts of such a journey, will find the book pleasant, but yet unpleasant. One can scarcely help but envy the medical brother who has had the opportunity to see so much and who has seen it with his eyes so wide open.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, MARCH 16, 1901. NO. 11.

ORIGINAL ARTICLES.

RECENT EXPERIENCES WITH ERYTHROMELALGIA.*

BY HENRY L. ELSNER, M.D.,

OF SYRACUSE;

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE IN THE SYRACUSE MEDICAL COLLEGE.

AT the meeting of the Medical Society of the State of New York held in 1897, I reported a case of erythromelalgia associated with Raynaud's disease in which there was a prolonged period of agonizing pain in the fingers of the right hand, burning, prickling sensations, the characteristic rose-colored fingers, while the whole hand was covered at the time of acutest suffering with thousands of sweat-drops. The temperature of the hand was always perceptibly increased and the pain was aggravated when the hand hung down; hence it was usually held up firmly by the patient to obtain relief. Finally the terminal phalanx of the thumb became cold, blue and shrivelled. There was a V-shaped line of demarcation, and, after a process of dry gangrene, it separated entirely, leaving the articular surface of the bone clear and smooth. The ultimate gangrene in this case was considered to be the result of secondary vascular change, a conclusion which is strengthened by the overwhelming evidence of changes in the arteries, particularly in the intima, consequent upon long-continued distention or vasomotor paralysis.

The position of the writer was strengthened by the facts which Thoma[1] had brought to our notice in *Virchow's Archiv*, which proved that compensatory changes take place in the arteries which have remained distended for a considerable time, and which in truth are too large for the blood which courses through them. In the case reported it was held that this compensatory effort finally caused complete occlusion in some of the smaller arteries supplying the terminal phalanx of the thumb, and death of the part resulted. The patient suffered but little pain, comparatively speaking, after this event. The hand always remained hot, and when hanging down became rose-colored and uncomfortable. She died of acute tuberculosis in eighteen months after the loss of the thumb phalanx.

All of the symptoms preceding gangrene were positive of the symptom-complex known as erythromelalgia and corresponded exactly with those given by Weir Mitchell and Lannois, whose differential methods were used to make positive the diagnosis. The possibility of the association of gangrene, Raynaud's disease or other necrobiotic processes has been denied by some writers. Among these is Weir Mitchell, to whom we are indebted for the first full consideration of the symptoms to which he finally gave the name of erythromelalgia.

In connection with the history of erythromelalgia, it may be interesting to note that Graves in 1843 described a peculiar condition of the extremities associated with symptoms much like those mentioned by Mitchell in 1872 and 1878, in which he suggested that the nerves and arteries of a part independent of the heart could affect local circulation sufficient to give rise to local symptoms of a peculiar and unique character. It has seemed that the symptoms of erythromelalgia are occasionally associated with processes of a destructive character, either through pathological changes in the blood-vessels, the peripheral nerves or from other causes, which remain purely speculative.

Three cases have been seen since writing my original paper on this subject; two of these cases will be considered carefully, and to these I wish to call your attention at this time. The third case was seen but once and could not be followed. The history, however, justified the conclusion that the patient, a man aged fifty years, without specific history, was suffering from an alternation of erythromelalgia and the first stage of Raynaud's disease. The red neuralgia persisted during several days, when suddenly the marble fingers of Raynaud's disease followed. These conditions had alternated with each other for some time. In this case there was no deep loss of tissue, but at the tips of the fingers there were several cup-shaped depressions showing the loss of epithelium in small plaques.

Case I.—William McM. was seen in consultation with Dr. Jacobson on July 1, 1897. He was sixty-four years of age, married, had been a contractor, vendor and finally a farmer. Thirty-six years ago he contracted syphilis. His subsequent history considerably abbreviated is as follows: In the summer of 1893 he first complained of pain, burning in character, associated with great heat and a prickling sensation in his right foot and most severe in his right second toe. During 1893 and until January, 1894, this pain recurred in paroxysms. It was always of the same char-

* Read before the ninety-fifth annual meeting of the Medical Society of the State of New York, Albany, January 29–31, 1901.

acter and always associated with great heat in the foot and with considerable redness. Early in 1894 the ball of the great toe of the right foot became exquisitely tender and painful. After this date it was noticed that at the time of greatest suffering the foot became hot, rose-colored, and was covered with thousands of sweat-drops, while the veins were always abnormally prominent and the arteries beat violently. It soon became apparent that the patient was worse when the foot was suspended. In 1894 his weight was 220 pounds. Early in 1897 he dropped to 150 pounds.

In June, 1894, he was thrown from his wagon and he supposed (until an examination proved to the contrary) that he had broken his leg. No bruises or scratches on his leg or any other part of his body were found. After this accident the pain was more severe, with all of its former accompaniments, extending to the neighboring toes and radiating upward beyond the ankle. Soon the left foot was involved in a similar process of red neuralgia with hyperidrosis. Both feet had become exquisitely tender and hypersensitive. The patient rested on his back much of the time. Almost from the beginning of the second year of his suffering and until his death there was a fine rhythmic tremor in the muscles of both legs, increasing as the disease progressed, and always increased during the acute exacerbations of pain and while the feet were dependent. With the progression of the disease there was more or less atrophy of the muscles of both legs, more advanced in the right than in the left leg.

Before the patient consulted Dr. Jacobson, he had been unsuccessfully treated by a number of physicians, and numerous diagnoses had been made. During the early days of Dr. Jacobson's treatment cauterization along the spine with large doses of iodide gave transitory relief; later, however, these remedies failed to control the pain and other symptoms. The patient had always been constipated and suffered considerably from gastric and intestinal indigestion.

About January 16, 1897, almost six months before I saw him, the middle toe of the right foot became gangrenous. The process remained dry and the surrounding tissue became dusky, while the appearances of hyperemia continued above these parts whenever the leg was held down. The gangrene advanced upward with increasing atrophy of the muscles of the right foot and leg until, finally, the fourth toe became dusky, and by October 21st much of the tissue of the right foot was gangrenous. All of the toes with the exception of the little one were involved. There was no pulse perceptible in the right dorsal pedis nor in the posterior tibial arteries. The left foot remained erythromelalgic without gangrene. Careful examination of the patient failed to give evidences of spinal or other central disease. The eyes as well as all the superficial and deep reflexes were normal. Physical examination on July 1, 1897, gave ample evidence of far-reaching arteriosclerosis. This degenerative process included the aorta, and wherever the arteries were palpable there was no difficulty in detecting the characteristic unevenness and their abnormal resistance. There was slight hypertrophy of the left ventricle. Urinary examination proved negative.

Long before I saw the patient his suffering became so acute as to keep him in bed with his head low and his feet in the air on a mountain of pillows. It was impossible to use the esthesiometer. The slightest pressure or draft intensified his suffering, and large doses of opiates were successful, with the posture treatment after July, 1897, in relieving only slightly the acute and persistent pain. With these symptoms the patient died of exhaustion January 5, 1898.

This is the history of a case of erythromelalgia covering a period of five years, with ultimate gangrene of the right foot, and with a persistence of rose neuralgia in the left with an underlying specific history and far-reaching arterial disease.

Case II.—On January 8, 1897, through the courtesy of Dr. Jacobson, Miss F., aged thirty-nine years, a tailoress, was referred to me. Her mother was living at that time, but has since died at the age of sixty years of cancer of the stomach. Her father died of diphtheria when thirty-three years old. She has two sisters who are living and are healthy. There were no evidences of neuropathic tendency or specific taint. She worked on heavy clothing, probably in an unfavorable environment. Her suffering commenced over sixteen years before I first saw her. During all these years she had the characteristic symptoms included in Weir Mitchell's original description of red neuralgia or erythromelalgia.

Her pain commenced in the palmar surface of the terminal phalanx of her left index finger. In addition to a severe paroxysmal neuralgic pain in this finger she complained of continuous discomfort; and early in her history it became evident that when the finger hung down it became rose-colored; paroxysms of intense suffering followed, with a burning, prickling sensation; there was throbbing and swelling, while the entire hand, more particularly the index finger, felt abnormally hot and soon became covered with innumerable sweat-drops. She noticed too that the pain was worse during menstruation, and that as time wore on the paroxysms became more frequent, the veins of the fingers and hand during the exacerbation of pain increased in size, while the arteries beat with increased force. Soon the index finger became hypersensitive and hyperalgesic, and there was a

fine rhythmic tremor involving the entire hand, more violent in the index finger.

During all these years and until the final radical treatment this tremor persisted. To prevent the extreme agony which finally became unbearable, this unfortunate girl worried through almost twenty years, holding her hand during her waking hours that it might not be brought in contact with any object, and that she might be spared the added suffering which was sure to follow when her hand was suspended. Her entire left arm remained unused and there was more or less atrophy, including the interossei. The smaller joints were stiffened. At times there were clonic spasms of the flexor muscles of the fore-arm. The greatest sensitiveness was found about the nail of the index finger. Cutting the nail increased the pain. The slightest touch with the points of the esthesiometer provoked pain and perceptibly increased the tremor. Heat aggravated the pain, while cold during the first few years seemed to give relief. Later, nothing ameliorated the acute suffering save the holding of the hand quiet in an upright position.

After this erythromelalgic condition had persisted for about ten years, there were two superficial ulcerations involving the skin on the palmar surface of the first and second phalanges of the index finger. These finally healed, leaving slight depressions covered with normal skin. The necrobiotic process was without influence on her pain; the finger continuing red and congested.

When she came to me there was no time when the index finger was without erythema or tremor, or when the hand was not abnormally hot and sweat-covered. About five years ago a small circumscribed gangrenous patch involving the tip of the painful finger appeared, which left a slight depression to be finally covered with normal skin. On this depression there was a deposit of horny epithelium, which renewed itself rapidly and broke off in plaques. A skiagram showed no changes in the bones of the hand. Hyperesthesia both of depth and surface was augmented.

Desperate, willing to make any sacrifice which might lead to relief, she consulted me in August, 1900. The symptoms were not materially changed from those already described. The esthesiometer could no longer be used because of increasing sensitiveness. The knee-jerks were noticeable in both legs; no ankle clonus present in either foot. The muscles of the arm and forearm gave normal response to electricity. All degrees of heat or warmth applied to the troublesome finger were overappreciated; there were no eye symptoms; the mental condition had always been normal; there were no symptoms referable to the lower extremities. The localization of the greatest pain in the index finger, its persistence during many years without evidences of brain, spinal or other peripheral involvement, the futility of medical treatment, seemed to justify surgical interference. Amputation of the index finger below the erythematous area was advised. Dr. Jacobson concurring, the patient readily consented. It was thought wise to sacrifice part of the metatarsal bone, which, as the result proved, made the ultimate deformity less prominent.

The improvement in the condition of the hand, and the return of the patient to a life of usefulness after a long period of suffering justified the sacrifice of the finger. There has been no pain in the hand during the past eight weeks, the patient has gained in weight, the tremor has disappeared except when fatigued, and to all appearances *the offending factor was removed with the finger.*

Dr. Steensland, to whom the finger was sent for examination, reported as follows on the microscopic examination of the specimen: "Tissues were hardened in Zenker's fluid. Sections were cut from the skin in the region of the second phalanx and at the tip of the finger, including the horn-like outgrowth; from the vessels and nerves at the base of the finger; and from the muscular tissue of the corpus. Sections were stained in hematoxylin and eosin. Sections of the nerves were also stained by Van Gieson's method for the central nervous system." "There is occasional slight thickening of the intima of both the large and the small arteries. About the small arteries are occasional foci of infiltration with lymphoid cells. Veins are apparently normal. The horn-like outgrowth occupies a slight depression in the general surface and consists of a thickening of the horny layer of the epidermis. Careful examination of the nerves, Pacinian corpuscles, sweat-glands, hair-follicles, and muscles shows nothing apparently abnormal."

A study of the cases reported casts no doubt upon the diagnosis of erythromelalgia. In speaking of the diagnosis of erythromelalgia, Weir Mitchell makes the following statement after giving the histories of two cases, one, a case of erythromelalgia, the second, one of Raynaud's disease: "Surely, no two more entirely separate groups of symptoms could be found; this cold, white hand, with its pale fingers, free from pain of any moment and more or less anesthetic, and now presently livid; this hot, deep-red foot, so painful that its torment brings out the sweat on the sufferer's brow."

In the cases here reported the destructive processes were not preceded by the corpse fingers or toes, but with opposite conditions, long-continued, and always associated with the circulatory changes which Weir Mitchell has aptly described as a "true vascular storm"; thus agreeing in every particular

with the original and subsequent description by Mitchell with, however, the addition of the gangrene and superficial loss of tissue.

The bibliography and references appended prove that our experience with erythromelalgia is not as yet a large one. In all probability, if all the reported cases were carefully scrutinized, we should not find their number much above 50. Among these there are, however, including my original case and those of this paper, ten or eleven which bear directly upon the association of the processes which are held possible in this paper. Morell-Lavalle[41] reported a case in which the symptoms of erythromelalgia alternated with those of partial local syncope. Mills[35] had the case of a woman aged twenty-three years, who after two years of persistent erythema of the extremities developed symptoms resembling the milder Raynaud phenomena. Dehio's[52] case has been frequently quoted. A small portion of the ulnar nerve above the wrist and an equally small piece of the ulnar artery were resected. In five months the tip of the little finger of the left hand became black and a small piece of bone with pus and blood escaped. In this case microscopic examination showed marked changes in the intima, which materially narrowed the lumen of the vessel. *There were no changes in the nerve.* Kahane[50] reports a case in which, as in the second case reported in this paper, there were superficial ulcerations, depraved nutrition of the nails and rhagades.

Sachs and Wiener[55] report the case of a man in middle life, without any evidence of other nervous or arterial disease, in which erythromelalgia developed in the left foot, and in which there was finally a dry gangrene of the second toe with a threatening gangrene of all the other toes. Amputation was followed by a satisfactory recovery. Sachs[55] says that he has met two cases of erythromelalgia associated with gangrene of the toes, and adds: "We must therefore modify Weir Mitchell's account and claim that in extreme instances of this disease gangrene may occur." In Wiener's[55] report of the microscopic examination, he says, "There is a marked arteritis affecting all the coats, but more particularly the intima." There were a few degenerated nerve-fibers, but the nerve-changes "were relatively slight."

Rolleston[53] reports the case of a man, twenty-nine years of age, with symptoms which have "affinities" with both Raynaud's disease and erythromelalgia. The symptoms of Raynaud's disease were atypical. There was redness of the hypersensitive skin made worse by heat and relieved by cold. Johannsen's[86] case reported by Oppenheim shows the association of erythromelalgia and Raynaud's disease, while Potain[87] has reported a case in which, as in the first case reported in this paper, there was gangrene on one side and erythromelalgia on the other.

In the first case here reported the underlying pathogenic factor was certainly the specific and sclerosed arteries. However slight the changes found on the microscopical examination of the arteries in the second case, the subsequent cure and the absence of changes in the nerves must prove that these were sufficient to cause the symptoms. It is an interesting and noteworthy fact that, in most of the cases in which microscopic examinations have been made, the greater changes have been found in the arteries, while the nerves have been only slightly or not at all changed.

The results of Sternberg's[85] experiences collected in his recent article on "Endarteritis und Endophlebitis Obliterans und ihr Verhältniss zur Spontane-Gangraen" are corroborative of the great rôle which the arteries play in these cases. His paper is a convincing contribution to the subject, for it is founded on the careful pathological study of six cases; five of these were young subjects in whom spontaneous gangrene resulted, while in some of the cases the erythromelalgic symptoms were an accompaniment; in all, however, the microscopical examination revealed more or less endarteritis obliterans *without change in the accompanying nerves or terminal plates.* The pains as a rule were worse at night and were aggravated by heat. The greatest changes were found in the intima.

Sternberg[85] concludes as the result of his investigation that the "cause of spontaneous gangrene is a fundamental endarteritis obliterans, which is provoked by a variety of noxious changes upon a weak and tardy local circulation with ultimate hypertrophy of the muscularis and an active tissue-overgrowth of the intima." Thoma's[70] original experiences, in which secondary arterial changes were found to take place and which have already been mentioned in connection with the case reported in a former paper, are corroborated.

The failure to find microscopic changes in the nerve-structures of a finger in which pain and other sensory symptoms have been in the ascendency during a period of twenty years is indeed surprising, but it is not at variance with the experiences already mentioned. Indeed Sachs[55] ends his paper with the statement that "surely erythromelalgia is as much an arterial as a nerve disease."

How do we account for the pain in these cases? In 1803 Nothnagel[82] and in 1894 Laache,[81] in considering pains of so-called vascular origin, called attention to the fact that the adventitia of arteries contained Vater-Pacinian bodies; and to this sensory terminal apparatus they pointed as the origin of the pain in these cases. Schlessinger's[83] theory is not tenable in our cases. He says that in these cases the *vaso nervorum* are de-

generated and finally cause the pain. This may occur, but in the cases reported and in those examined by Sternberg[85] there was no such process. It is not uncommon for circulatory disturbances to cause pain by irritation of the sensory end apparatus in the skin. Erb[77], in his article on "Intermittent Claudication and Other Nervous Disturbances Following Vascular Changes," agrees that endarteritis is the cause of the pain.

The differential diagnosis of erythromelalgia and acroparesthesia must be considered. The latter condition first brought to our notice by Nothnagel[82] in 1867, later by Schultze[84] in 1890, resembles erythromelalgia only because of the presence in both of paresthesia and hyperesthesia. In no other particulars are these conditions similar. Acroparesthesia is associated with numbness and falling asleep of the fingers and formication. There are but few objective sensory disturbances; oftener there are none. There are no vascular symptoms; there is considerable motor weakness; if there is change in the color of the fingers, they are pale, not red; the hands are abnormally cold; in some cases the temperature is reduced from ½° to 2° C. Friction, walking and movement of the parts reduce the discomfort, while in erythromelalgia these aggravate the torture. There is greater intermission in the symptoms in acroparesthesia, while in erythromelalgia they finally become continuous; in erythromelalgia the reflexes are exaggerated, while in acroparesthesia they are normal. The vascular storm is absent in the latter; decidedly in evidence in the former. Of 162 cases of acroparesthesia 150 were women; only 12 were men. The majority of cases of erythromelalgia are found in men. Acroparesthesia affects anemic, cachectic and overworked adults; in middle life and women at the climacteric, particularly those who work in cold water. In erythromelalgia there are, besides the predilection of the disease to attack the lower extremities, complications referable to the digestive system with far-reaching central, spinal or peripheral changes in many cases.

At the present time erythromelalgia cannot be dignified as a disease *per se*. Scanning the literature which has accumulated, we are surprised to find the great variety of diseases which claim erythromelalgia as an attendant.

In addition to the cases to which the writer has referred, the following are noteworthy: Schenck's[60] case with ascending degeneration of the posterior columns of the cord; Woodnut's[75] case was associated with myelitis; Collier[12] reports 10 cases associated with various spinal, system and indiscriminate lesions; Auerbach[3] reports two cases, in one of which a postmortem examination revealed degenerative changes in the posterior nerve-roots of the lumbar and sacral nerves without degeneration in the cord substance, while the blood-vessels were found normal. This is the only postmortem of a case of erythromelalgia on record. Nieder[44] reports a case of erythromelalgia with eye symptoms prominent, choked disc with vascular dilatation, Eulenberg[18], one case of brain tumor with hemorrhagic retinitis, and consequent changed visual field; Hoffman[79] mentions an interesting case of acromegaly associated with erythromelalgia, in which the patient was twenty-three years of age. She had had erythromelalgia since her sixth year, when finally the characteristic changes in the hands and feet of acromegaly followed; Henoch's[26] case was one of erythromelalgia following hemiplegia and hemihyperidrosis, death finally resulting from angina pectoris[78]; and Levy[31] reports a case resting on a hysterical basis, cured by hypnosis, in which erythromelalgia was associated with Raynaud's disease.

THE TREATMENT OF THE HEART IN TYPHOID FEVER AND OTHER INFECTIOUS DISEASES.

BY ALBERT ABRAMS, A.M., M.D.,

OF SAN FRANCISCO.

The maintenance of cardiac vigor is always a source of anxiety in the treatment of typhoid fever, pneumonia and other infectious diseases. Since the inauguration of systematic hydrotherapy in typhoid fever, no experienced physician can gainsay the life-saving functions of this therapeutic method. While the antipyretic effect of the cold bath is a recognized factor in treatment, it must be regarded as possessing only a secondary influence. The chief action of the bath is on the circulatory system. By maintaining the vigor of the latter apparatus, we succeed in providing for the necessary resistance to the typhotoxins. Despite the salutary effects of the cold bath, we are constrained to recognize the following disadvantages: (1) The apparent brutality of the method; (2) the discomfort and suffering attending its employment; (3) the difficulty often encountered in its employment in private practice; (4) the hardship and the necessary assistance in executing the method; (5) the occasional collapse symptoms following the method.

There is no therapeutic method which is universal in its application and individualization is as imperative in typhoid fever as it is in other diseases. Whenever an error is perpetrated in the hydrotherapeutic treatment of typhoid fever, it is most emphatically in the direction of misinterpreting the effects to be attained by the use of the cold bath; and such an error is always in evidence when the thermometric curve and not the condition of the heart is taken into consideration. No matter how decided the antipyretic action of the bath, if cardiac vigor is compromised or fails to be improved, the end result of hydrotherapy is defeated. The cold bath may temporarily overcome the lethargy or even inhibit the delirium and nervous symptoms yet withal, such results are achieved through the agency of shock and not through the legitimate channel of stimulation of the nerve-centers presiding over important functions. I have frequently witnessed the employment of cold baths in the treatment of typhoid fever by practitioners with dogged pertinacity despite alarming heart-collapse symptoms, the finality of the procedure taking only into account a reduction in temperature; and, when the latter condition had been achieved, the cold bath was regarded as effective.

The following theories have thus far been advanced in explaining the action of the cold bath in typhoid fever: (1) It possesses a powerful stimulating action on the circulatory apparatus and nervous system. (2) It exerts an antipyretic action. (3) It stimulates the nerve-centers presiding over the functions of respiration, circulation, digestion, nutrition and excretion. (4) The flux and reflux of blood between the periphery and viscera are facilitated. (5) Leucocytosis is produced.

Until we are willing to dismiss antipyresis as the great desideratum in the treatment of typhoid fever, we cannot hope to achieve any better results in this disease than are at present obtained. A departure from the conventional method of treatment, however, appears easier owing to the tendency in recent years to discredit the advantages accruing from antipyresis, hydro- and pharmacotherapy. In attempting to solve the rationale of hydrotherapy, the theory which most cogently appeals to reason is that which presumes that the action of the cold bath is secured

by stimulation of the peripheral cutaneous nerves. If the latter theory is correct it needs corroboration and the following observations are adduced in its support. I have endeavored to show in several contributions[1] that we are able by cutaneous irritation to powerfully influence the pulmonic and cardiac vigor by inducing what I have called respectively the lung and heart reflexes. The nature of the cutaneous stimulant is of but little moment, it may be mechanical, chemical or electrical, the result being always the same, namely, dilatation of the lungs and contraction of the myocardium. The physiological results of lung dilatation (*lung reflex*) are the conveyance of more oxygen to the blood and consequently, a better nutrition of the tissues. Myocardial contraction (*heart reflex*) is marked by reduction of the pulse-rate, together with an increase in volume and force. One can be easily convinced of the influence which cutaneous irritation exerts on the action of the heart by auscultating the mitral sounds in a typhoid-fever patient, especially during the stage of convalescence. The slightest pressure of the stethoscope in the mitral area will cause the heart sounds to become feeble or even inaudible. The elicitation of such results is, however, not uniform. There are limited areas which are not responsive to the test while others are. For convenience of description I will refer to the latter as cutaneous cardio-inhibitory areas.

To relinquish hydrotherapy as conventionally employed, the surrogate suggested must possess certain advantages and I believe that by the use of balneotherapeutics after the Schott method, such advantages can be attained. I know of no means better adapted for maintaining the vigor of the heart in typhoid fever, pneumonia and other infectious diseases, than the use of the carbonated baths. The reduction in temperature after the carbonated baths is relatively slight. Such reduction is evoked by dilatation of the cutaneous vessels, thus increasing heat-radiation. If we are disposed to disregard the effects of the carbonated baths on the temperature, we will observe decided advantages in favor of the baths. If, however, we regard temperature reduction as a necessity, then we may alternate the carbonated with the cold baths or we may even incorporate the ingredients necessary for generating the carbonic acid, in the cold bath. I have frequently observed that, when heart-collapse signs follow the cold bath, they may be prevented most effectually by the means just suggested.

Recognizing, as I do, that the salutary effects of hydrotherapy are provoked essentially by cutaneous stimulation I have had recourse in the treatment of a few cases, to a procedure which for convenience is called a *friction bath*. The method is succinctly as follows: The patient is first rubbed or sponged with alcohol and this is followed by vigorous cutaneous friction until the skin glows. The results of this method are at once evident in the circulatory apparatus and nervous system. The following is a typic record taken by the nurse in a typhoid-fever patient on the thirty-sixth day of his disease. Pulse records were made at five-minute intervals following the friction bath.

Time.	Pulse.	Temp.	Resp.	Remarks.
1:30 P.M.	100	100.1	18	Pulse previously dicrotic and difficult to count; has lost dicrotism and is easily counted.
	100			
Friction bath.	96	100.2		
	90			
	90		18	
6:00 P.M.	120	102.8	24	
	118			Slightly delirious.
Friction bath.	116			
	100	02.4	18	
7:00 P.M.	90	102.8	18	
	88			Quiet and restful.
Friction bath.	86			
	84	102.7	18	

The friction rub was ordered whenever the temperature was above 102.6° F. or when the heart showed evidence of enfeeblement. The latter sign was elicited by reference to the intensity of the heart sounds by means of a stethoscopic attachment which I have called the stethophonometer.[1]

In nearly all the cases where the friction bath was employed in lieu of the cold bath, the temperature reduction was slight, but the stimulating effects on the heart and nervous system were pronounced. I wish parenthetically to show how suggestion even enters into the prosaic pursuit of nursing. I instructed an intelligent nurse to keep a record of the pulse in a case of typhoid fever, and the following was the result: Before friction bath, pulse counted at five-minute intervals, 92, 90, 96, 100. After friction bath, 96, 98, 104, 108.

On expressing surprise at the record, which was contrary to my expectations, she replied, "I supposed that is just what the friction bath would do. On the following day she gave me the following record: Before bath, 94, 92, 96, 98. After bath, 80, 78, 72, 68.

The latter record was also a disappointment and on the same day, I made her repeat the record with the same results. A control record, made by myself immediately after, demonstrated that the nurse had erred most grievously; her desire to please me as she supposed caused her to err to the extent of about 8 pulse-beats on an average per minute. I believe that the real benefits from the natural or artificial Nauheim baths are dependent on cutaneous stimulation by the billions of gas-bubbles contained in the carbonated baths.

Of late, I have employed with excellent results, not only in the treatment of typhoid fever and pneumonia, but in chronic diseases of the heart, a procedure which I have called the *siphon method*. It is suggested for its simplicity and efficiency. The patient is prepared in the usual manner for taking a sponge bath and beyond this no disturbance of the patient is necessary. Then a siphon bottle containing the carbonated liquid

[1] Medical News, Jan. 7, 1899.

New York Medical Journal, Jan. 13, 1900.

[1] Made for me by the Shoenberg Electrical Co., San Francisco.

is gradually discharged over the surface of the body, notably on the thoracic region. If one wishes to comply with the requirements of the Schott system, although stimulation is not so pronounced, the siphon bottle may before use be immersed in hot water until the requisite temperature is attained. Within a few minutes, one may note after the employment of the siphon method, a reduction of the pulse from 10-20 beats a minute which rate is maintained for a varying period of time. The pulse becomes likewise endowed with more strength and there is a feeling of exhilaration such as rarely obtains after the cold bath. Pulse-tracings taken in a convalescent typhoid patient, with an extremely weak heart, have demonstrated the favorable action of the siphon method.

A REPORT OF THREE CASES OF THORACIC ANEURISM TREATED BY SUBCUTANEOUS INJECTIONS OF GELATIN.*

BY LEWIS A. CONNER, M.D.,
OF NEW YORK;
PROFESSOR OF CLINICAL MEDICINE IN THE CORNELL UNIVERSITY MEDICAL COLLEGE; ATTENDING PHYSICIAN TO THE HUDSON STREET HOSPITAL.

The announcement by Lancereaux[1] in 1897 of his results in the use of subcutaneous injections of solutions of gelatin in the treatment of five cases of aneurism of the aorta has, very properly, excited wide interest and, also, no inconsiderable amount of discussion. The use of gelatin for this purpose was suggested to him by the observations of Dastre and Floresco[2] who found that gelatin when introduced into the blood produced a very marked heightening of its coagulative power.

It is not my purpose here to discuss generally the use of gelatin injections in aneurism. The whole subject has recently been carefully reviewed by Sorgo,[3] Ewart[4] and Futcher[5] of Baltimore. The last-named also records his results in nine cases of aneurism treated in the Johns Hopkins Hospital. My object is simply to relate my own experience with this therapeutic measure in three cases of thoracic aneurism which have come under my care during the past year at the Hudson Street Hospital. I must say, at the outset, that in none of the three cases was it possible to carry out the treatment sufficiently long to draw any definite conclusion of its value as a curative agent. The experience was sufficient, however, to demonstrate certain objections to the method and certain difficulties in the way of its administration.

Lancereaux's directions are that a solution of 4 or 5 grams of white gelatin be made in 200 c.c. of normal salt solution and that this be sterilized in a flask at 120° C. Separate samples of this are kept at 38° C. for several days and those specimens which become turbid or fail to solidify on cooling are discarded. Of this two or two-and-a-half per cent. solution 200 c.c. are injected into the subcutaneous tissue of the thigh. After injection the patient is kept absolutely quiet. The aneurism should not be palpated. The injections are to be repeated every six or eight days and should be continued until 15 or 20 have been given. Lancereaux thinks this method applicable chiefly to saccular aneurisms.

Huchard[6] believed the two-per-cent. solutions of gelatin to be rather dangerous, in that they tended to produce too rapid coagulation, and preferred to use a one-per-cent. solution. The same view was later taken by Lancereaux, who used the one-per-cent. solution in somewhat larger quantity (250 c.c.). In each of my own cases the initial injection consisted of a two-per-cent. solution, and the subsequent ones of a one-per-cent.

Lancereaux states that such injections cause no pain and produce neither local nor general reaction. These statements have not been entirely confirmed by most of the other investigators, nor do they correspond with my own experience.

Case I.—Aneurism of Descending Portion of Arch. Three Injections. No Improvement. Death from Rupture into Esophagus. Autopsy. An Italian laborer, aged fifty years, was admitted to hospital April 6, 1899. He denies syphilis and alcoholism, and has always had a laborious occupation. For two years he has been troubled with burning pain in the left side accompanied by a whirling, gurgling sensation. Describes pain as passing from precordium around left side to region of scapula. Of late has been obliged to sleep in sitting position because of dyspnea. On admission his temperature was 98° F., respiration, 28, pulse, 108.

Physical Examination.—Fairly nourished, muscular man. Face anxious. Respiration moderately rapid. Cutaneous veins over left side of chest and left arm and shoulder prominent and tortuous. Over back of chest between angle of left scapula and vertebral column is a slightly projecting, rounded pulsating tumor. Pulsating area measures 6 cm. in diameter. Near the center of this area is a projecting spot 2 cm. in diameter.

Palpation.—Apex beat in fifth space, 10 cm. from median line and rather feeble. No other pulsation anteriorly. Behind, pulsation over area described. Most marked over the prominent center. Gentle palpation reveals erosion of ribs corresponding to this protruding center. No tracheal tugging. Radial pulses synchronous and of equal size. Arteries thickened and tortuous.

Percussion.—Dulness everywhere behind sternum and to a short distance on either side of the manubrium sterni. Below this dulness blends with area of cardiac dulness. Behind, on left side, well marked dulness from third dorsal spine to 1 cm. below angle of scapula.

Auscultation.—Over upper left chest inspiratory murmur almost lost; expiration of soft bronchial character. Behind, over left chest, as far down as dulness extends, absent breathing

* Read before the Section on Medicine of the New York Academy of Medicine, April 24, 1900.

and distant voice. Heart sounds as follows: At apex first sound muffled and prolonged; soft blowing systolic murmur over third left space. Urine normal.

There is profuse expectoration of greenish, purulent blood-stained sputa. For ten days after admission there was slight gradual improvement in cough and expectoration. April 21st all other treatment stopped. Injection of 185 cm. of two-per-cent. solution into left thigh.

On April 26th and May 1st, injections of one-per-cent. solution were given. These were all followed by slight local discomfort and by some temperature. As a result of these injections no change either in physical signs or in subjective symptoms, could be recognized. Four days after third injection patient had a violent attack of coughing, followed by vomiting of a large amount of bright blood, collapse and death.

Abstract of Autopsy.—Heart very small. Muscle light colored and rather soft. Valves competent. Transverse portion of arch of aorta shows moderate cylindrical dilatation. At beginning of descending portion the artery regains its normal caliber. Immediately beyond this a large saccular aneurism, 15 cm. in diameter, is given off posteriorly. This communicates with the aorta through a circular opening 3 cm. in diameter. The aneurism has eroded the bodies of the fourth, fifth, and sixth dorsal vertebræ, and has completely eroded the fourth, fifth, sixth, and seventh ribs near the angles. It communicates with the esophagus by an oval opening, 4 cm. long. The wall of the sac is very irregular in thickness, in places being made up of old laminated clot, 3 cm. thick, and in other places being free from clot. There is no evidence of recent clot-formation. Left bronchus is much compressed at its origin. A great part of lower lobe of left lung shows a condition of consolidation apparently of long standing. Stomach enlarged and abnormally low in position. It is filled with clotted and fluid blood. Remaining viscera show only unimportant changes.

Case II.—Aneurism of Transverse and Descending Portions of Arch and of Innominate Artery. Seven Injections. Severe Local Pain. Slight Improvement. A housemaid, unmarried and forty years old, was admitted to hospital May 18, 1899. Denies history or symptoms of syphilis. Fairly marked alcoholic habit for several years. Acute articular rheumatism six years ago. Dyspnea on exertion for past two or three years. Six months ago she began to have intermittent pain in right supraclavicular space and noticed some swelling there. One week later pain became fairly constant and has since persisted. Some increase in dyspnea. Also irritation of throat with dry cough. On admission the temperature was 98° F., respiration, 26, pulse, 92. Urine normal.

Physical Examination.—Fairly nourished woman of good color. Slight dyspnea. Eyes prominent. Right pupil wider than left. Reaction normal. Prominence of superficial veins of both sides of neck and both shoulders. In right supraclavicular space is seen a small pulsating swelling. With each pulsation the sternal end of right clavicle moves slightly.

Palpation.—Swelling the size of a small walnut just above right clavicle and extending down behind bone. Pulsation systolic in tissue. Systolic pulsation also felt immediately to right of first bone of sternum. Apex beat in fifth space 12 cm. from median line and of heaving character. Distinct tracheal tugging. Pulses equal. Arteries show no marked changes. Behind, slight systolic pulsation inside of left scapula between spine and lower angle.

Percussion.—Precordial dulness reaches to right border of sternum and extends upward behind manubrium sterni to suprasternal notch. In first and second right intercostal spaces the dulness extends one-third the length of the clavicle. It also extends slightly to left of the manubrium. Left border of cardiac dulness extends 1 cm. to left of nipple line. Behind, moderate dulness on left side from spine to angle of scapula.

Auscultation.—Short double murmur at apex which grows louder toward base of heart. Harsh systolic murmur over tumor above clavicle. Behind, faint double murmur heard over area of dulness on left side.

After patient had been kept in bed for six days gelatin injections were begun. Between May 24th and July 8th seven injections were given, the first containing two per cent. of gelatin, the subsequent ones one per cent.

The first injection was followed by slight local pain and by a slight rise of temperature. The second, by severe pain, some redness and tenderness and a moderate temperature (102.6° F.). The remaining five injections were each followed by such severe pain as to require the use of morphine to make it bearable. The pain began very soon after the introduction of the fluid and was often intense for eight or ten hours. The area about the point of injection was swollen and red, but there was no distinct induration nor was there ever suppuration. Some febrile reaction was always noticed, but no chills occurred. The pain was present whether the injections were made in the thigh or in the abdominal wall. The suffering of the patient was finally such that we did not feel justified in continuing the treatment. After the second injection the slight pulsation felt posteriorly disappeared.

On her discharge some days after the last injection the patient's condition, as compared with that upon admission, was as follows: The pain in right side of neck was less constant and less severe, but was felt over a somewhat larger area. The cough and irritation of the throat had disappeared. The slight pulsation posteriorly had disappeared, but anteriorly it seemed to be rather more distinct. The swelling in neck had slightly increased in size, but was less tender. Patient

was seen again five months later, at which time no appreciable change in the signs could be recognized.

Case III.—Aneurism of Transverse Portion of Arch. Three Injections. Severe Local Pain. No Improvement. Bartender, forty-five years old. Admitted to hospital June 19, 1899. Denies syphilis. Alcoholic habit excessive up to three years ago; since then moderate. Always well up to nine years ago. Then suddenly developed high-pitched, husky voice which has since persisted. For past two months gradually increasing dyspnea. This morning was awakened by a violent attack of spasmatic dyspnea, which was present on admission. No pain at any time. Temperature, 101° F., respiration, 38, pulse, 104.

Physical Examination.—Patient poorly nourished and anemic. Marked dyspnea. Pupils unequal, left being moderately dilated and sluggish in its reaction to light. Right pupil small and with normal reaction. Complete paralysis of left vocal cord. Veins over upper left chest and left side of neck distinctly dilated. Pulsation and slight tumefaction in suprasternal notch and left supraclavicular space. Slight pulsation in first left intercostal space. Apex beat in sixth space 10 cm. from median line. Action regular and forcible. Pulses synchronous, equal in size. Arteries somewhat thickened and tortuous. Distinct tracheal tugging. Well-marked dulness behind first bone of sternum and in first and second spaces for a distance of 3 cm. to left. Below this the dulness merges with that of precordium. A loud systolic murmur is heard over base of heart and in vessels of neck. Also a blowing diastolic murmur over pulsating area and less distinctly over base of heart. Aneurism gives no physical signs posteriorly. The severe dyspnea persisted for some hours, but gradually subsided and thereafter was never more than slight.

Four days after admission patient was given his first injection of gelatin in the right thigh. This was followed by moderate pain and slight temperature. Ten days later a second injection was given, followed by quite severe pain. After an interval of eight days a third injection was made into the abdominal wall. This was followed by such severe pain as to require morphine. The patient was so loth to submit to further injections after this experience that the treatment was discontinued. During the period of treatment there was a gradual, but distinct increase in the size of the pulsating area and in some of the subjective symptoms.

In all these cases the greatest care was exercised in the preparation of the gelatin solutions. The gelatin was carefully selected; the solutions were filtered and then tested as to their reaction lest they should contain some acid. They always, however, gave a neutral reaction. The sterilization and the introduction of the fluid was also done with the greatest care. The injections were made by means of a large aspirating syringe and the fluid was introduced as nearly as possible at a temperature of 100° F.

To recapitulate briefly: Of the three cases, two received three injections and one seven. In two cases the injections had to be discontinued because of the severe local pain. In the third the pain was only slight. In one case, that receiving seven injections, a very slight improvement could be detected. In one case a slight increase in symptoms was noted, while the third case died of rupture of the aneurism while under treatment and the autopsy showed no evidence of recent thrombus-formation, although the condition, that of a large sac with a small communication with the aorta, was an especially favorable one for clotting. Aside from the pain and local irritation no untoward symptoms were observed in any of the cases as a result of the injections.

I am not ready to conclude from these cases that the method has no therapeutic value since in none of the cases was it possible to carry out the treatment fully. Lancereaux believed, however, that he could see very distinct improvement even after a single injection. Certainly no such satisfactory result was apparent in any of the present cases. Futcher gives his results in nine cases as follows: While no case was cured there was a considerable diminution in the size of the aneurism in one case and in several others an appreciable reduction in the subjective symptoms referable to pressure. He believes the treatment to have some merit. Futcher also found that the injections were frequently very painful and were followed by local reaction, fever and even chills.

It must be remembered that the administration of twenty injections would consume approximately five months of time and that during this period the patient must be kept absolutely quiet in bed. Rest in bed for such a length of time would, of itself, in many cases produce a distinct amelioration of the subjective symptoms and even some improvement in the physical signs.

My experience in these cases has at least convinced me that, whatever the curvative value of the treatment, its usefulness is seriously impaired by the severe pain which frequently follows the injections.

OBSERVATIONS UPON THE AMŒBÆ COLI AND THEIR STAINING REACTIONS.[1]

BY CHARLES F. CRAIG, M.D.,
OF SAN FRANCISCO;
ACTING ASSISTANT SURGEON, U. S. ARMY; PATHOLOGIST AND BACTERIOLOGIST TO THE U. S. ARMY GENERAL HOSPITAL, PRESIDIO OF SAN FRANCISCO, CAL.

Because of their diagnostic importance and the fact that they are often mistaken for other structures occurring in the intestinal tract, a brief description of the amœbæ of dysentery

[1] Published with the permission of the Surgeon-General of the United States Army.

may be of interest. It is safe to say that among the parasites causing disease in man there is not one which more often has been blamed unjustly for disease conditions than has the *Amœba coli*. This is because it has so often been said to be present in the feces when in reality it was not, other things slightly resembling it having been mistaken for it. Large intestinal epithelial cells, leucocytes, collections of anemic blood-corpuscles, monads and the *Cercomonas intestinalis* have all been shown me as the veritable amœba, and that by men otherwise well informed in such matters. To know the amœba one has to have seen it, and it is one of the most difficult of parasites to recognize from text-book descriptions.

As is well known, Losch in 1875 was the first to describe this organism, and numerous observers have since confirmed his researches. Among these may be mentioned Kartulis, Kruse, Koch, Manson, Councilman, Lafleur, Dock and Leuckart.

The organism belongs to the Protozoa, class Rhizopoda. It is simply a mass of protoplasm, provided with a more or less distinct nucleus, hence the ease of mistaking it for other similar unicellular organisms or even large cells.

When at rest the organism may be circular or oval in shape; if arrested while in motion, it may be irregular. It is more refractive than other cells occurring in the feces, with the exception of the monads, and the protoplasm has a peculiar, faintly greenish hue, almost exactly like that of certain malarial crescents. Its size varies greatly, from 5 to 35 mmm. in diameter, but most of the amœbæ seen ordinarily measure from 15 to 25 mmm. in diameter. While many authorities claim that the amœbæ seen in any one case are all about the same size, this has not been my experience, the amœbæ differing widely, some being very large, others small. The shape, also, varies much, some being perfectly circular, others oval, and others irregular in shape.

As ordinarily described the organism is said to consist of two parts, an inner, granular portion, called the endoplasm and an outer, clear portion, called the ectoplasm. This description has been the cause of mistaking the organism for large cells, the inner portion corresponding to the granular nucleus and the outer portion to the protoplasm. As a matter of fact, this differentiation cannot be made out in all cases by any means, and very seldom in amœbæ which are not motile. While, doubtless, the two portions mentioned exist, too much stress is laid upon this characteristic, resulting in confusion, as only the experienced observer can in most instances distinguish them. The organism possesses a nucleus, but this is often difficult to make out, especially in moving amœbæ. It is situated somewhat to one side and is very refractive; its outline is often more or less irregular. The endoplasm forms most of the substance of the organism, is of a peculiar, faintly greenish hue, very finely granular, resembling finely-ground glass, and generally shows a number of perfectly circular or oval, so-called vacuoles. The vacuoles are spaces within the protoplasm of the organism, clear cut in outline and collected in groups within the protoplasm. Many of them seem to contain two or four very refractive dots resembling micrococci. Although these spaces are generally called vacuoles, it is by no means certain that they are so. Certainly they do not resemble the vacuoles in blood-corpuscles and it always appears as though they do not penetrate entirely through the organism, their floor seeming to be formed by a thin, veil-like layer of protoplasm. It is often impossible in certain instances to believe that these peculiar spaces are vacuoles, and it is by no means settled that they are so. These spaces vary slightly in size and in number in different amœbæ. The small amœbæ seldom show them, but the large ones seem often to consist entirely of a collection of them, surrounded by a small amount of the protoplasm. It would seem from this that such an amœbæ might be a sporulating body, as the oval spaces resemble very strongly the segments of the sporulating malarial plasmodia save that they are larger. The amœbæ generally show more or less material within their protoplasm which they have absorbed. They often contain red blood-corpuscles, bacteria, pigment particles, etc. Often these inclusions are so numerous that the structure of the amœba is entirely hidden. When it can be seen the ectoplasm consists of a narrow rim of a clear, light green color surrounding the darker endoplasm.

As to the mobility of the amœba, they are always motionless in feces which have not been kept warm, as a temperature below 75° F. renders them immobile, but it is often possible, after preparing a specimen upon a slide from such feces, to render the organisms motile by gently warming the slide over an alcohol lamp. The motility of the organism varies, but it is generally a slow ameboid motion, the organisms throwing out rounded protoplasmic processes, exactly as do leucocytes. These processes are always perfectly clear and formed by the ectoplasm, and these are often the only portions of the organism which shows the differentiation into ectoplasm. In rare instances the movement is rather rapid, the processes being thrown out quickly and the whole organism moving in an eccentric jerky manner. More often, however, the change in position is very gradual, and only careful watching will detect it. Often, also, the organism does not change its position, but merely its shape, the protoplasmic processes being projected and retracted, sometimes so very slowly that close scrutiny only will detect them. Often also, a peculiar

undulatory motion of the border of the organism is noted, exactly like that occurring in the malarial parasites.

When the temperature is that of the body the amœba are most active and progress by an almost imperceptible projection and flowing into such projection of the mass of the organism. When, however, the temperature is low, it can be seen that the protoplasmic projection gradually becomes larger until at last the granular endoplasm flows into it. This process is repeated and thus the organism changes its position.

The color and refraction of the amœba should serve to distinguish it from cellular material, as intestinal epithelium, it being of a peculiar, faint green color and very refractive, which is marked enough so that even with a ⅔-inch objective it can be picked out from the surrounding cellular matter. These properties, however, do not serve to distinguish it from the monads and cercomonads, which are also greenish in color and refractive, but they are much smaller than the large amœbæ and much more actively motile, not throwing out protoplasmic processes, but moving by means of flagella. To one who has seen the amœbæ these organisms could never be mistaken for it, but mistakes have been made, especially when the observer had only the text-book description as a guide.

To sum up the amœba is a round oval or irregular protoplasmic body, varying in size; motile or immotile, the motility being ameboid in character and, when present, being generally moderate; pale or faint green in color; refractive, with sharply-cut border, and containing a circular or oval, lighter colored, space, known as a vacuole. In some a darker colored nucleus can be distinguished and in the immotile organisms a darker colored central or eccentric portion, containing the vacuoles and comprising the greater part of the parasite, and known as the endoplasm, can be seen, surrounded by a narrow or much smaller layer, lighter in color and clear, known as the ectoplasm.

Nothing is known as to the method of reproduction of the parasite, but it is generally believed to be by sporulation. If this is so, it is possible that the so-called vacuoles are in reality spores, the mother parasite eventually rupturing and thus setting them free. Reasoning from what occurs in other similar organisms, this seems the most probable method of reproduction. It is impossible in observing a large circular amœba, filled with the oval or round spaces so that only a thin strip of protoplasm remains visible, to resist the impression of its resemblance to the large, segmenting tertian plasmodia, just before the segments separate and become free. Another interesting analogy between the two parasites is that in both, solutions of sulphate of quinine arrest all motion immediately, and destroy them. In many amœbæ I have noticed the so-called vacuoles change their position, floating with the protoplasmic currents within the amœbæ.

The Staining Reactions of the Amœba Coli in Feces.—It is not a very difficult matter, where the amœba are numerous in the feces, to obtain well stained specimens if sufficient care is taken in their preparation. While, undoubtedly, the amœbæ show to greater advantage when stained in sections of tissue, the method of staining them in feces is most practicable and useful, and if the smears are made sufficiently thin, the organisms will show very perfectly. So little is said in the recent text-books regarding the appearances presented by the stained amœbæ that a somewhat detailed account of their staining reactions is of interest. Like all protozoan organisms, the nucleus stains with more or less difficulty, but I have found that carbolic fuchsin stains it, as well as the nucleolus, very easily and deeply, while methylene blue stains it dimly and often not at all.

I have tried a large number of different staining solutions, but have found that only three are really worthy of use, in that they are sure, rapid and show the minute structure of the amœba well. These are: Loeffler's methylene blue solution, carbolic fuchsin solution, and thionin solution. Of these solutions, Loeffler's methylene blue is the quickest and best stain for general use, while the carbolic fuchsin solution is by far the best where it is desired to stain the nucleus and nucleolus, as well as certain peculiar bodies within the protoplasm of the amœba. Toluidin blue is also a good stain. The thionin differentiation method recommended by Mallory, which often gives beautiful results in staining amœbæ in tissue, gives but fair results in the staining of the organisms in the feces and can hardly be said to be differential, as other structures in the feces take and hold the stain. It is a useful stain, but methylene blue is far better and much more easily applied.

Having found a specimen of feces containing numerous amœbæ the smears are prepared as follows: Several cover-glasses are thoroughly cleaned and placed in a row upon the edge of the table. With a sterilized platinum loop a small flake of mucus is picked out of the feces and placed upon a cover-glass. This is repeated, a minute flake of mucus being placed upon every other cover-glass. The intervening clean cover-glass is then dropped gently down upon the glass containing the mucus, and then the two are slid apart, very gentle pressure being used in doing so. By proceeding in this way a dozen or more very even, thin smears can be secured in a few minutes' time. The smears are then placed face up in equal parts of alcohol and ether and allowed to harden for thirty minutes. If the feces are warm when the preparations are

made, many of the amœbæ will be hardened while undergoing amœboid motion. After hardening, the smears are ready to stain.

Staining Reactions with Loeffler's Alkaline Methylene Blue Solution.—The smears are stained in this solution for from three to eight or ten minutes; about five minutes gives the best results; they are then washed in distilled water and mounted in Canada balsam.

The amœbæ take the blue stain very well, staining almost as deeply as the nuclei of the epithelial cells. In such stained preparations three stages of the amœbæ can be detected. The smaller amœbæ staining comparatively uniformly; larger ones, staining less uniformly and containing one or more vacuoles; and still larger ones, riddled with vacuoles and staining very deeply. The smaller or young amœbæ stain much more intensely than the larger ones, and with the methylene blue seldom show a nucleus. No vacuoles can be seen, nor do they often contain red blood-cells. The protoplasm is of a rather dark blue ground color, with small oval or round lighter blue areas scattered through it. The smallest amœbæ do not show these light areas, but stain almost uniformly throughout. No distinctions can be traced between the ecto- and endoplasm. These small amœbæ are generally round, but sometimes show small pseudopodia which generally stain very intensely. Some of the small amœbæ show a peculiar mottled appearance, light and dark stained areas alternating throughout their protoplasm. These small forms are evidently young amœbæ.

In all the preparations the most numerous forms of the amœbæ are those to be described. They are large, generally round or oval in shape, although if the preparations are made when the amœbæ are active, many of them are irregular in shape, showing pseudopodia. The protoplasm in these amœbæ stains irregularly, but no distinct differentiation into ecto- or endoplasm can be made. One portion of the amœba stains very densely and there is a gradually shading off into a light blue color. In the irregular forms this is most noticeable, the pseudopodia staining very dimly, due to the fact that they are composed of ectoplasm which takes the stain but dimly. Some of pseudopodia, however, stain very intensely, due probably to the fact that the endoplasm had flowed into them just before hardening. These fully grown amœbæ show from one, to three or more, large vacuoles, which are entirely unstained, but besides these there are numerous small, oval or round, very dimly-stained areas, scattered throughout the protoplasm, which are evidently not vacuoles and correspond to the same areas observed in the very young forms. Scattered between the oval, dimly stained areas, are very deeply stained small portions of protoplasm. The staining phenomena of these amœbæ exactly resemble those of the large, segmenting tertian malarial plasmodia. The vacuoles and the dimly-stained areas are entirely distinct, the dimly-stained areas being oval or round, much smaller than the vacuoles, having a dim outline and evidently not penetrating the organism as do the vacuoles. Many of these amœbæ contain red blood-cells which do not stain, but show as round, or irregular, light green areas, scattered through the protoplasm of the parasite. In a few of the amœbæ very deeply stained, almost black, oval-shaped structures can be seen, generally arranged near the periphery of the organism, and resembling bacilli, save that they are too large and are often irregular in shape.

In preparations stained for some time, some of the large amœbæ show a very deeply-stained nucleus, situated, as a rule, eccentrically, but sometimes near the center. It stains a dark lilac and contains numerous more deeply-stained, almost black granules. Sur-

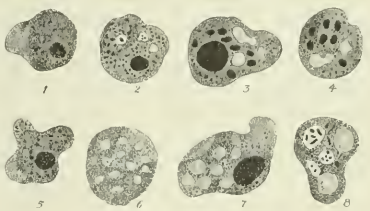

Fig. 1. Young amœba, showing deeply-stained nucleus, and dimly-stained ectoplasm. No vacuoles. Obj., $\frac{1}{12}$ inch. Fig. 2. Young amœba showing deeply-stained nucleus and so-called vacuoles. Obj., $\frac{1}{12}$ inch. Stain, toluidin blue. Fig. 3. Full-grown amœba showing deeply-stained nucleus and oval spots; also vacuoles. Obj., $\frac{1}{12}$ inch. Fig. 4. Amœba showing deeply-stained oval spots, but no nucleus. Obj., $\frac{1}{12}$ inch. Stain, toluidin blue. Fig. 5. Young amœba showing deeply-stained nucleus and endoplasm, dimly-stained ectoplasm. Obj., $\frac{1}{12}$ inch. Stain, toluidin blue. Fig. 6. Very large amœba, staining almost uniformly throughout, and filled with red blood-corpuscles, which are greenish in color. Obj., $\frac{1}{12}$ inch. Fig. 7. Full-grown amœba showing deeply-stained nucleus, dimly-stained ectoplasm, and several red blood-corpuscles. Obj., $\frac{1}{12}$ inch. Fig. 8. Full-grown amœba showing two red blood-corpuscles, and three dimly-stained pseudo-vacuoles, containing deeply-stained rods and dots, probably bacterial in nature. Obj., $\frac{1}{12}$ inch.

rounding this nucleus is sometimes seen a more lightly-stained area with a deeply-stained, almost black border. Besides blood-corpuscles, the protoplasm of these amœbæ contains numerous deeply-staining rods and dots, evidently bacteria of various kinds. Besides the two forms of amœbæ described, large round forms are seen, containing numerous vacuoles and staining more or less dimly. No nucleus can be demonstrated in these forms, nor can the small, oval, unstained areas be seen. In most instances these amœbæ are simply riddled with vacuoles, the amœba consisting of a stained shell perforated by vacuoles. Many of these show evidences of pigmentation. These are probably degenerate amœbæ, undergoing, just as does the plasmodium of malaria, vacuolization and pigmentation. It is a significant fact that such amœbæ never show any inclusions in the way of blood-corpuscles or bacteria.

Staining Reactions with Fuchsin.—Smears are stained with carbol fuchsin for from five to ten minutes, washed in water and mounted in Canada balsam. This stain is especially useful in demonstrating the nucleus, which stains very beautifully. The same structures are seen in amœbæ stained by this method as by methylene blue, but in addition the nucleus, nucleolus and certain other details can be made out. The nucleus stains a deep red, is usually situated eccentrically, near the edge of the parasite, probably at the juncture of the ecto- and endoplasm, but it may be more central. It contains a small, more deeply-stained nucleolus, and a few almost black granules, while the nuclear substance contains minute, more deeply-stained areas. The nucleus is round or oval in shape and regular in outline. As noted before, the large amœbæ containing great number of vacuoles, do not show any nucleus.

Besides the nucleus and its contents, the fuchsin stain demonstrates with the protoplasm of many of the amœbæ some very peculiar bodies, the nature of which it is impossible to conjecture. Scattered irregularly through the protoplasm are variously-shaped particles, stained a deep brownish red, and especially numerous near the nucleus. These particles are oblong in shape, as a rule, flat and are much larger than any bacterium. They present often a fractured extremity, as though they were crystalline in structure, and it may be that they are certain crystals absorbed from the feces.

In all preparations from the feces, however stained, amœbæ are seen evidently undergoing fragmentation. Numerous knob-like outgrowths are seen, almost entirely separated from the parasite and some which are separated. These fragments stain deeply, and the fragmenting parasite usually shows a normal appearing nucleus, thus showing that the process is a degenerative and not a reproductive one.

Little need be said of the thionin stain. It gives similar results to those just described but is not nearly as satisfactory as the methylene blue or carbolic fuchsin.

This much can be said to have been demonstrated by the study of stained specimens of the amœbæ:

1. That vacuolization is a degenerative process, as the young amœbæ show no vacuoles, the full-grown healthy ones, few, while the amœbæ in which they are most numerous are degenerate bodies, showing neither a nucleus nor inclusions of any kind.

2. That there occur in all but the degenerate forms of amœbæ, small, round or oval, unstained areas, uniform in appearance, and most numerous in the large, full-grown forms, and entirely absent in the vacuolated shells of amœbæ. These areas resemble similar areas observed in stained, segmenting malarial plasmodia, which are, in them, due to the young spores, which take the stain but faintly. Reasoning from analogy, it may be that these areas in the amœbæ are also spores.

3. That in the protoplasm of the amœba, there occur peculiar structures, evidently not bacterial in nature, the significance of which it is impossible to decide. It may be that they are certain crystals which occur in the feces and which have been absorbed by the amœbæ.

4. That degeneration of the amœbæ takes place in two ways, *i.e.*, by vacuolization and by fragmentation.

In closing this paper I desire to express my obligations to Colonel Girard, Commanding Officer of the Hospital, for his uniform encouragement and assistance.

A PRELIMINARY NOTE ON THE RELATION OF THE FORM OF THE TUBERCLE BACILLUS TO THE CLINICAL ASPECTS OF PULMONARY TUBERCULOSIS.[1]

BY HENRY SEWALL, PH.D., M.D.,
OF DENVER, COL.

During the winter of 1889-90, I gave some attention to a problem which had previously been suggested to me by Dr. Welch, of Johns Hopkins University. It was to determine whether any relation exists between the characters of the tubercle bacillus, its staining reactions and varieties of form, and the clinical symptoms of pulmonary disease. The work was done under exceptional advantages at the Adirondack Cottage Sanitarium, where, from first to last, more than seventy patients were the subject of inquiry. A summary of results was published in the Medical News, July 25, 1891.

The investigation proceeded from two directions: (1) Pure cultures of tubercle bacilli were studied as to their form and staining qualities; (2) tuberculous patients under observation were divided into arbitrary groups, according as their clinical signs and symptoms seemed to enable one to discriminate between (*a*) those who were recovering; (*b*) those who were simply holding their own, and (*c*) those who were manifestly failing.

The sputa of all these individuals were carefully examined, and the tubercle bacilli found therein were compared as to form and in some cases as to their staining properties. The pure cultures of tubercle bacilli consisted of tubes kindly furnished me by Drs. Councilman and Abbott, of Johns Hopkins, Drs. Vaughan and Novy, of Ann Arbor, and Dr. Trudeau, director of the Adirondack Sanitarium. All the cultures were old and probably, as will be assumed, of low virulence, except one furnished by Dr. Trudeau, which was new and the infective power of which had recently been found to be very great. The conclusiveness of this phase of my work suffered greatly from the lack of facilities to incubate new

[1] Read before the Colorado State Medical Society, 1000.

cultures on various media and to test their virulence by inoculation.

It is now a matter of elementary knowledge that the tubercle bacillus is distinguished from most other microbes by the fact that, after being stained with an aniline dye, it resists decolorization by acids much longer than most bacteria. The relation of the bacilli to stain was tested in the following way: Cover-slip preparations were made from the various cultures, and they were stained for a definite time in carbol-fuchsin. The slips were placed on the microscope stage, upon a specially-prepared slide, permitting active irrigation with fluid without movement of the specimen. When a stream of very dilute nitric acid was allowed to flow under the preparation, the smear quickly lost its color, but the retention of color on the part of the bacilli from the fresh, virulent culture was preceptibly longer than in the case of those from the old and presumably non-virulent cultures. That is to say, the virulent bacilli resisted decolorization longer than the non-virulent. If the acid did not remain too long in contact with the specimen, its removal by a stream of water was followed by a return of color, and this alternation of reactions was produced a number of times.

But, as in the first case, the final decolorization of the virulent bacilli required a more prolonged action of the acid than did that of the other forms. As these observations were repeated day after day, the difference in resistance to the action of acids exhibited by the various cultures gradually diminished. It is a plausible assumption that the virulent culture, exposed to the diffused light of the laboratory, little by little lost its toxic power and with it the tenacious hold upon the aniline dye. I made no extended observations on the morphology of the bacilli found in pure cultures, but it is worth recording that the forms found in the virulent culture were uniformly like those presently to be described as characteristic in the sputa of rapidly-failing cases of tuberculosis, while in the non-virulent cultures the bacilli presented the features preponderating in the expectoration of "good" clinical cases. It is hardly necessary to say that the tubercle bacillus, while a very distinctive organism to the trained eye, presents much variety in its appearance. The length of the bacillus is said to vary from one-quarter to three-quarters of the diameter of a human red blood-corpuscle, the thickness being one-fifth to one-sixth of the length.

When studied in sputum, tubercle bacilli appear to me to present the following well-marked varieties of form, with more or less complete gradations between: (1) A very short, relatively-broad rod; (2) a long form represented by a chain of rods; (3) a long form homogeneous in structure; (4) a long form of a beaded appearance, as if composed of a string of spores. Many investigators have described a branching variety of the tubercle bacillus, which some have regarded as a result of degenerative growth, others, as the sign of its relation to higher biological species. The occurrence of such departures from type are not likely to attract the average observer. That a definite species of bacteria may appear under widely different forms has been abundantly demonstrated, Westbrook having recently analyzed the varieties of the diphtheria bacillus, and Adami shown that the colon bacillus may appear as a diplococcus.

It seems to be the common belief that the composition of the culture medium and the conditions of growth as to supply of oxygen, heat and moisture, have much or all to do with this morphological diversity. A difference in the toxic virulence of the various forms is only suspected.

The present paper makes no pretense of presenting explanations of facts, but is limited in its scope to the practical question, Does the form of the tubercle bacillus as found in the sputa, have any relation to the physiological condition of the patient? In the clinical classification of patients I made in the Adirondacks, I was impressed with the fact that the failing cases, with active destruction of lung tissue, produced sputa characterized by a preponderance of the shortest rod-like forms of bacilli. In cases that were doing well the short and jointed germs were few or wanting, the prevailing forms being slender, homogeneous rods of greater or less length, the substance often being broken into spore-like droplets. In old chronic cases, in which there had been a great loss of tissue, but in which the disease had been fairly-well arrested, or in which the malady had made such extensive havoc that the maintenance of life itself was a demonstration of the low virulence of the infecting organism, the bacilli were long and beaded. A few observations were made to test the resistance exhibited by these different forms to decolorization by acids. This difficult subject was not sufficiently explored to support definite conclusions, but so far as the observations went it appeared that the short rods held their color longer under the action of acids than did the other forms.

To-day I am strengthened in the opinion, formed nearly eleven years ago, that the form of the tubercle bacillus, as it is demonstrated in the sputum, is an important indication of the virulence of the tuberculous process, and as a corollary I will venture to suggest that it is a useful guide to prognosis. It is a truism to say that the tubercle bacillus is always dangerous and may always be deadly. Most of those who were classed as "good" cases in my Adirondack list are long since under ground. As practical physicians we are familiar with the enormous influence of habits and environment upon the well-being of the tuberculous subject. Yet we are continually facing anew the strange fact that of two consumptives, both in similar physical condition, with apparently equal chances for recovery, one progressively gets well, but the other gradually slips backward, here a little, there a little, until no hope remains. Again, in the temporary physical backsets to which every tuberculous subject is liable, one case recovers perfectly as from a

passing indisposition, but another rises broken and permanently hurt. It has seemed to me that the form of the bacilli found in the sputa has great significance in the discrimination of these classes of cases one from the other.

The short, deeply-staining rod or chain of rods of moderate length is the usual form in many active cases. The long rods, particularly if irregularly broken, betoken a milder process, and the chains of spore-like beads characterize the very chronic cases which make us wonder at their tenacious hold on life. If there be a *good* form of the tubercle bacillus it is, as seems to me, a rather long, slender rod, ill-staining or staining irregularly, as if the body of the microbe were irregularly corroded on the sides. It is found in cases apparently passing on to cure. Sputa of the same individuals examined month after month have seemed to me to vary in their bacillary characters with the state of the patient as regards the disease.

RHINOSCLEROMA.*

BY H. JARECKY, M.D.,
OF NEW YORK.

The case which I have the pleasure of presenting, would perhaps be better described by the term scleroma respiratorium than by the title of this article. However, the title adopted in this paper seems to be so universally accepted for the condition that I have used it as above. The disease is so rare and peculiar, that I have thought that a short historical sketch would be interesting.

The malady was first described by Hebra[1], in 1870, from the observation of nine cases, four male and five female. Since then many writers have added their mite of knowledge, furthering the study of the disease. Its home seems to be in Russia and Austria. In the United States, according to Dr. Freeman,[2] there have been only half a dozen cases reported previous to his, and in Central America about twenty-three.

It is characterized, according to Hebra, by a gradual thickening or infiltration of the integument or mucous membrane of the ala or septum. Nodules then form, which are circumscribed, flat or elevated, hard and painful to the touch, and are covered by normal or slightly wrinkled epidermis of a dark red or shining color. Glands and hair-follicles are absent from the integument.

The disease progresses painlessly and insidiously, the nodules project from the nose and its side, and cause the organ to be deformed, thickened and widened, well shown in Freudenthal's[3] patient. The whole mass is as hard as ivory. Thence it spreads to the angles of mouth, lips, the opening of the mouth, as in Mikulicz's[4] case, scarcely admitting the tip of the little finger. Sometimes the cheeks and eyebrows are attacked. The malady also works its way backward through the nasal passages, causing stenosis, and attacks the pharynx, palate, uvula, larynx, trachea and bronchi. It may also spread through the lacrimal duct and, as in Pick's[5] case, through the Eustachian tube to the external ear. The tongue is rarely affected. The progress is by a non-inflammatory infiltration of the tissue which exhibits no tendency either to break down or to form ulcerative processes.

Although Hebra considered that the external nose was always affected in this ailment, it was soon discovered that other parts of the respiratory tract might be primarily affected, as in our patient. Ganghofner[6] demonstrated that *chorditis superior hypertrophici chronica,* and Türck showed that Stoerck's *blennorrhœa chronica* belonged to the same class, although these had always been considered separate laryngeal affections. In 1882 Frisch[7] demonstrated bacteria to be present in rhinoscleroma.

Microscopically the infiltration commences with numerous small cells, among which are large or spheroidal (Mikulicz) ones. The bacteria are usually found in, and only rarely between these cells. Later these round cells are transformed into spindle-shaped ones and finally into a dense connective tissue. The bacteria occur in pairs or fours, encapsulated in a colloid substance. They resemble Friedländer's pneumococcus and take the Gram stain.

When the degeneration takes place and the connective tissue is formed, one sees scar-tissue of all shapes and varieties producing all sorts of contractions. The disease progresses so slowly that no symptoms are noticed for some time, but later the sufferer complains of a dryness in the nose and throat and a difficult nasal respiration. If the larynx or trachea is affected, there is troublesome cough and hoarseness and dyspnea finally causes the patient to seek medical aid. A peculiar fetid odor, distinct from that of atrophic rhinitis with ozena, is usually present, but is not found in the patient whom I now present.

Yetta S., thirty-two years old, a native of Russia and residing in the United States for eleven years. Parents died while she was yet a child, so that nothing is known of them, and one sister is living in good health. She has always been well and has been married fourteen years, having six healthy children ranging from ten months to thirteen years old. She has not had any miscarriages. About four years ago she noticed a slight pain on swallowing, and upon examination a growth was found in the throat for which nothing was done, a mouth-wash only being prescribed. For the past nine months, she has experienced some difficulty in breathing. This has been gradually getting worse and it was for the dyspnea that she sought treatment.

Upon examination I found the nose to be the seat of an atrophic rhinitis and filled with a frothy discharge, the membrane being very much swollen. In the mouth, bands of connective tissue passed backward to the palate from the back part of gums. The tonsils and uvula were missing. Hanging from the right posterior pillar

* Read before the Society of the Alumni of the City Hospital, November, 1900.

was a growth the size of a large nut, with a very fine pedicle. Posterior rhinoscopy could not be made at the time. The epiglottis was found to be atrophied and folded upon itself, so that on the under surface, the right and left halves were in apposition. Stenosis was so marked that no view of the larynx could be obtained.

I snared the sessile growth and submitted it to Dr. Beaman Douglas, Pathologist at the Manhattan Eye and Ear Hospital, for examination, who reported that it consisted of tonsillar tissue. Suspecting a case of rhinoscleroma, the bacilli were looked for, but were not found. Posterior rhinoscopy then revealed cicatricial bands extending from the posterior pillars to the lateral walls of the pharynx.

In arriving at a diagnosis many things had to be considered. Syphilis was excluded by antisyphilitic treatment, absence of pain during disease, the number of healthy children, no loss of tissue in the scars and by there being no lymphglands enlarged.

Tuberculosis was excluded by the absence of constitutional symptoms and there was no broken-down necrotic tissue, which would appear as the disease extended over such a long period. Lupus by freedom of pain and ulceration and burn from caustic, by history.

The diagnosis of rhinoscleroma was emphasized by the absence of pain, length and duration of disease, loss of uvula, only a smooth scar marking its place, and the amount of cicatricial bands.

The disease attacks patients between the ages of fifteen and forty-five years. The prognosis is unfavorable, as no curative treatment has as yet been discovered. Where the disease processes do not encroach on the larynx or trachea, the disease has no effect upon the general health. The treatment, in a general way, consists in relieving externally the deformity and internally the stenosis of the nasal passages, nasopharynx and of the larynx.

Cutting away the growth and rhinoplastic operations have been advised. Injections of arsenic, salicylic acid, carbolic acid, chloride of zinc, nuclein, rhinosclerine, etc., have been tried with varying success. When the nares are closed or narrowed, excising portions, using galvanocautery, dilating with tents, etc., have been recommended.

In this patient the laryngeal stenosis is the only disturbing symptom, and this is being treated with Schrötter's intubation tubes with relief, although there is still some dyspnea. Upon casting a general glance over the case, I think that we must conclude that the disease commenced in the back part of the uvula and soft palate, and thence spread to the mouth, nasopharynx, pharynx, larynx and trachea.

The process seems to have come to an end in the upper parts, but is probably active in the larynx and trachea. The occurrence of the pendulous growth of atrophied tonsil tissue can only be accounted for by the process having occurred in the tonsil, and the resulting marked contraction of the connective-tissue formation having caused the separation of the part.

CLINICAL MEMORANDUM.

SUBGLOTTIC GROWTHS; REPORT OF CASES WITH EXHIBITION OF IMPROVED INSTRUMENTS.[1]

BY ROBERT C. MYLES, M.D.,
OF NEW YORK.

The recognition of the difficulties which I have experienced in removing some benign growths from the subglottic region in certain patients has prompted me to bring this subject before you. After trying and failing with nearly all the forceps and instruments that have been advocated, I constructed the one which I present to you in conjunction with this paper. The ideas were obtained from Sir Morrell MacKenzie's tube-forceps and Dr. Dundas Grant's double-hinged, diamond-shaped laryngeal forceps, and was made for me by Ford & Co. of New York City.

The chief interference with the success of an attempted operation in the subglottic region is due, at times, to the uncontrollable cough and glottic spasms, which shut off the operative field. In cases of benign growths it is especially desirable that no injury should be done to the healthy parts of the vocal cords and laryngeal tissues, and the ideal instrument wanted is one that will remove only so much as will fall within the jaws, which are closed at the distal end. I would suggest the use of this instrument in cases of subglottic papilloma occurring in children, but thus far I have not been fortunate in finding a suitable patient since the instrument was constructed.

I note that this spasmodic closure of the larynx is no new obstruction. Sir Morrell MacKenzie, in his remarkable work on "Growths in the Larynx," published in 1870, in Case LXXIX. of his 100 consecutive ones, says: "This growth proved a very difficult one to extirpate, as the vocal cords became spasmodically approximated when any instrument was introduced within the larynx. A very great variety of instruments were accordingly used. The first pieces were removed with the tube-forceps; at a later period I used the common anteroposterior laryngeal forceps, and, finally, a portion was taken away with Stoerk's wire guillotine."

[1] Read before the sixth annual meeting of the American Laryngological, Rhinological, and Otological Society.

One of my most interesting cases was that of the Rev. Mr. T. C., age twenty-eight years, who applied to me in June, 1898. He said that three years previously his voice began to lose in tone and vibration, and grew worse from that time until he had some growths removed in March, 1897. Two months afterward hoarseness began again, and he had more growths removed. He seemed to be comparatively well, with a fair speaking voice until a few weeks previous to coming to me when he had a hemorrhage, which apparently came from the larynx.

When I examined him, both ventricular bands were covered with wart-like excrescences which extended upon the posterior surface of the epiglottis. Both vocal cords were covered with papillomatous growths which extended downward over the subglottic region and were much more prolific on the left than on the right side. I had no difficulty in excising and removing the growths from the surface of the larynx, above the vocal cords, with the tubal-forceps as well as the MacKenzie cutting forceps. Attempt after attempt to remove the subglottic growths was followed by failure and this after many applications of solutions of cocaine, varying in strength from ten to one hundred per cent. Finally I succeeded in removing the growths with a modification of the forceps that I present to-day. The growths removed would number somewhere between fifty and one hundred. The patient has had no difficulty for the last year and is filling a responsible position in one of the largest churches in New York City, and now has a clear and resonant voice.

Fig. 1.—The instrument consists of a handle with finger-ratchet, extension Schroetter tube, and a revolving, unilateral forceps. Its mechanism is similar to that of Dundas Grant's forceps.

Another interesting case, Mrs. X., age fifty years, presented herself, complaining of hoarseness, difficulty in speaking and violent laryngeal spasms. Examination revealed a pale growth about ten mm. long; its middle third was situated beneath the processus vocalis, one-third of the growth extending beneath the respiratory glottis; the anterior third extended beneath the vocal glottis. This patient was most intractable when any foreign agent was introduced into the larynx. The spasms and coughs were violent and intense, applications of strong solutions of cocaine which were applied at intervals for an hour, did not seem to control the reflex phenomena. I was specially anxious to obtain a deep specimen of this growth for a microscopical diagnosis. I had used various forms of cutting and excisor tube-forceps, and succeeded in removing only small portions of the growth after many trials. Finally I made one prolonged and desperate effort to remove all of the growth in sight, this was accomplished with the instrument presented, after a two-hours' seance, during which time I used strong solutions of cocaine in a liberal manner, in addition to large doses of bromide of potash and a hypodermic of sulphate of morphine and atropine.

The author remembers with regret the case of a little child with multiple papilloma of the larynx and subglottic space, and believes that, if the instrument presented could have been used, the little patient's life might have been saved. Laryngotracheotomy was performed by a general surgeon in the writer's presence; the operation was a complete success in every detail, and every step of the operation was most skilfully carried out. The growths, covering the subglottic space, which seemed to be the ones that were causing almost complete suffocation, were thoroughly removed, but septic bronchopneumonia caused a fatal end two weeks later.

I commend the instrument for your consideration and trial, in non-malignant, infraglottic growths in childhood, as well as in adolescence.

MEDICAL PROGRESS.

Source of Blood in Urine.—Joseph Wiener, Jr. (*N. Y. Med. Jour.*, Mch. 9, 1901), first attempts to discover from what part of the urinary tract the blood comes, then seeks its cause. In early life stone in the bladder, tuberculosis of prostate or bladder, gonorrhea, sarcoma of kidney, or renal disease following an exanthema may be found. Adults have urethral

stricture, stone and new growths of bladder and kidney. In old age enlarged prostate, stone and newer growths predominate. Blood appearing between the acts of micturition is from the urethra; that appearing at the beginning of stream is prostatic or from deep urethra. Clots at beginning or end of clear urination are urethral, prostatic or vesical. In kidney hemorrhage the blood is intimately mixed with the urine. In renal hematuria, movable kidney, and renal stone the hemorrhage may appear and disappear suddenly. Rest relieves hemorrhage due to stone, or movable kidney, but may fail to influence that from tuberculosis or malignant growth. Long or short thin clots denote renal hemorrhage, long thick clots, urethral hemorrhage. If from bladder, prostate or urethra the blood readily sinks in the urine, but kidney blood remains intimately mixed with the urine. If the ratio of albumin to hemoglobin is above 1 to 16, there is albuminuria as well as hemorrhage and therefore probably nephritis. A careful examination of all the organs may show a cardiac lesion, tuberculosis, or malaria, and thus aid in diagnosis. Urethral hemorrhage is chiefly due to stricture or traumatism, prostatic hemorrhage to enlargement, stone, new growth, or occasionally to varicose veins, bladder hemorrhage to stone, tuberculosis or new growth, and renal hemorrhage to stone, tuberculosis, tumor, injury, and nephritis. Vesical tuberculosis is most frequent between 16 and 25 years, the urine is very light, odorless, feebly acid, sometimes containing tubercle bacilli; the stream is often arrested on account of pain, the bladder is irritable at night, bright hemorrhage may appear suddenly not influenced by rest; there may be a few drops of blood at end of urination accompanied by straining; there are distinct periods of quiescence uninfluenced by violent exertion, sudden relief of suprapubic pain and rapid cessation of pain in glands after urination and persistent post-scrotal pain; vesicle calculus is most frequent in adults, the urine is turbid, with mucus, pus, oxalates, urates, or phosphates; the stream is arrested involuntarily; the irritability of the bladder ceases at night; the hemorrhage ceases with rest and is most profuse at end of stream; there are no distinct periods of quiescence except with rest, the pain often persists after emptying the bladder, and there is no post-scrotal pain. In renal calculus the hemorrhages are usually small and frequent, in tumor, profuse and at irregular intervals, and the pain may be worse at night. Frequency of urination at night occurs in renal tuberculosis, but only in the daytime in calculus.

Preservative for Suprarenal Extract.—Boric acid, glycerin, or weak alcohol will preserve the gland for some weeks, but materially weaken its physiological effect. Camphor by its odor prevents detection of decomposition. Silver and mercury preparations are precipitated and render the extract practically worthless. By experiments on animals and subsequent tests clinically, Seymour Oppenheimer (*N. Y. Med. Jour.*, Mch. 9, 1901) has found that an almost permanent solution can be made by adding gm. 4.0 (℥i) of dried suprarenal to gm. 30.0 (℥i) of one-per-cent. solution of resorcin, and that the hemostatic and vasoconstrictor properties are not affected.

Biological Test for Human Blood.—The differentiation between human blood and that of animals is a problem of highest importance from a forensic point of view but as yet no test has been discovered which is infallible. Uhlenmuth (*Deutsche med. Woch.*, Feb. 7, 1901) describes a reaction which he is still engaged in elaborating and which promises to be the most reliable yet known. Its underlying principle is the fact that the blood of warm blooded animals, when small amounts of the blood of an animal of a different species are thrown under the skin, responds by forming bodies which when added to the blood of any animal of the species which was used to furnish the material for injection produce a well-marked physical change in it. For example if small quantities of defibrinated human blood are injected into the peritoneal cavity of a rabbit at intervals of 6-8 days, after 5 or 6 injections certain specific substances appear in the animal's blood. If to a weak solution of human blood in physiological salt solution a few drops of serum obtained from such a rabbit are added, a distinct turbidity occurs which on standing develops into a flocculent precipitate while similar dilutions of the blood of other animals (18 species have already been tested) give absolutely negative results. The reaction is extremely delicate and is effective even with traces of blood obtained from dried spots after four weeks of exposure to the air.

Incubation in Yellow Fever.—There are three distinct classes of patients to be considered from this point of view, *viz.*, those who go from a clean to an infected environment and remain there until the fever developed; those who go from an infected to a clean environment and there remain until the fever appears; and cases in which there has been only a single short exposure to infection. As can be seen the latter is most definite, but even here there is a chance of carrying the infection by clothing or other means so that incubation does not begin until some tnme after exposue. Henry R. Carter (*Med. Rec.*, Mch. 9, 1901) found that in Class I. the fever developed in from three to sixteen days after the first exposure; in Class II. from one to eight days after the latest exposure, nearly all developing by the third day; and in Class III. the incubation was from three to eight days, half of the cases showing fever on the third day.

Acute Gastric Ulceration.—N. Heineman (*Med. Rec.*, Mch. 9, 1901) considers that even an arteriole, if eroded in only a small part of its circumference so that it cannot retract or form a clot, may be a source of dangerous hemorrhage. The acute ulcer has no indurated edges and may be so small as to be easily overlooked. It is most often found near the cardia in the grand cul-de-sac, or on the anterior wall near the greater curvature, a situation in which chronic ulcer is seldom found. Usually sudden and excessive hemorrhage is the first sign. Exceptionally there are nausea, gastric pain, vertigo, and syncope; and when there is no vomiting, sudden pallor with thready pulse, chills, or convulsions may lead to the suspicion of ulcer. The condition must be differentiated from rupture of aortic or miliary aneurism, cirrhosis of liver, cancer, and chronic ulcer. Usually the acute ulcer appears suddenly in a person previously in normal good health. The treatment consists of absolute physical rest, rectal alimentation for three or four weeks, and an ice-bag over the stomach. Ergotin hypodermically, and intravenous injections of serum should be used. Dieulafoy's serum is 8 gm. chloride of sodium and 10 cgm. nitrobenzoate of caffeine in one liter of water. Hayem uses 5 gm. of chloride of sodium and 10 gm. of sulphate of sodium to one liter of water. Preparation for operation should be made and if the loss of blood continues the stomach should be opened and the ulcer carefully sought for and stitched up.

Dysbasia Intermittens Angiosclerotica.—This condition, which is an intermittent lameness of vascular origin, is very rare and was first described by Charcot in 1854. It occurs usually in persons past middle life. They are seized after walking a short distance, occupying perhaps five to ten minutes of time, with a helpless, cramp-like feeling in the legs, so severe as to render further progress impossible, though after a few moments' rest they can do their short stint again. While the patients are at rest and during the first few moments of exertion there is no trouble. Examination between seizures shows that one or more of the pedal arteries and even the popliteals are without pulsation, and as a result the foot may be cool and slightly pale, or red, or blue, according to circumstances. The arms are never affected. The cause of this condition has been variously conjectured, but nothing is positively shown. The disease is chronic and does not tend to recovery. Sometimes an improvement is brought about by such means as iodide of potash, moderate warmth, prolonged galvanism with the feet resting in tubs of warm water, cardiac tonics, and studious avoidance of exciting causes. James J. Putnam (*Boston Med. and Surg. Jour.*, Feb. 21, 1901) reports a case of this rare condition in a man seventy years of age, with a remarkably good history and physical condition. He had had one attack of dizziness in which he was precipitated from his chair to the floor. This may have been due to a cerebral lesion of arterial origin. For two months an intense sense of muscular fatigue in the legs, amounting almost to pain, recurred every time the patient walked more than one-eighth of a mile. This quickly disappeared on resting. The pain usually appeared first in the left calf, then in the right, and then extended upward to the thighs and hips, the knees not being affected. He then feels that he must stop, and that if he went on his joints would grow rigid and he could not move. On awakening in the morning or after a rest he feels perfectly well. He is not neurasthenic and mental work causes no fatigue. The calf of the left leg was found slightly cooler than the right and perhaps a little less firm. The left knee-jerk was slightly less than the right. The toes of the left foot could not be flexed dorsal quite so far as those of the right. Other movements were normal. The galvanic reaction of the left peroneal nerve was slightly less than that of the right. Only two of the pedal arteries could be felt to beat and one of these could be scarcely felt. Treatment carried out, as indicated above, brought about no change. Finally, the patient undertook to give himself a kneading of the calves morning and night, and soon he began to improve. He has continued this treatment and can now walk one or two miles without much difficulty. The writer is inclined to think that the best explanation of the condition is that it is a vascular spasm.

THERAPEUTIC HINTS.

Ichthyol Ointment.—W. T. Slevin (*N. Y. Med. Jour.*, Mch. 9, 1901) recommends the following for both superficial and deep inflammations:

℞	Ichthyol	gm. 3.0	(gr. xlv)
	Plumb. iodid.	3.0	(gr. xlv)
	Ammon. chlorid.	0.7	(gr. x)
	Petroleum, q. s. ad.	30.0	(℥i)

Vaginitis.—Use warm injections of a tablespoonful of the following in one liter (one quart) of water:

℞	Resorcin	20 parts.
	Ac. salicyl.	2 "
	Cupri sulphat.	
	Betanaphthol	0.25 "
	Aquam ad.	1000 "

Apply tampons impregnated with

℞	Salol	gm. 3.0-8.0 (gr. xlv-℥ii)
	Neutral glycerin.	gm. 250.-0 (℥viii)

And insert a suppository of

℞	Acetanilid	gm. 1.0	(gr. xv)
	Ac. tannic	0.50	(gr. viii)
	Ext. hyoscyam.	0.25	(gr. iv)
	Sacchar lactis	10.0	(℥vi)

—*Jour. de méd. de Paris*, Feb. 17, 1901.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada

Per Annum in Advance	$4.00
Single Copies	.10
With the American Journal of the Medical Sciences, Per Annum . . .	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, MARCH 16, 1901.

THE MEDICAL PROFESSION AND THE SOCIAL EVIL.

There are now only two contagious diseases that are not submitted to the regulation of municipal and State boards of health. Needless to say these are the venereal diseases. Of gonorrhea, Professor Neisser of Breslau, the discoverer of the gonococcus, said in the article on the subject which he read before the International Conference on Venereal Diseases at Brussels and which was contributed by him to the Medical News for January, 1900, that it is the most contagious of diseases except measles. Syphilis is known to be very violently contagious. Passing exposure to the active agent of the disease may produce it. It was not difficult over ten years ago for an American syphilographer to find in medical literature 20,000 cases of innocent syphilis. Most of these were due to accidental contamination.

The watchword of present-day medicine is the prevention of disease and especially of contagious disease. When two of the most important contagious diseases are left absolutely uncared for things are just as they should not be. No reason can justify inaction in the face of the dangers from these intensely communicable diseases. At the Brussels Conference the agreement of delegates gathered from all over the world was that at the present time the attempt to enforce police regulations of prostitution is inadvisable. Americans who have seen something of the inner workings of so-called police regulation in Paris, Vienna and Berlin, have very little confidence in the system as applied. There is an open acknowledgment of the necessity for evil that is distinctly lowering in its ethical tendency. The cooperation of medical men in the system gives a sense of security against venereal contagion that is not justified by the work done nor its results. Finally the increase of clandestine prostitution, despite the enforcement of police regulations, has shown that an effective registration and medical examination system is under present living conditions in our large cities a practical impossibility.

The Brussels Conference did offer one promisingly helpful suggestion as the result of its deliberations. It was that proper means should be taken for a more widespread dissemination of up-to-date knowledge with regard to venereal diseases. Our views as to the significance of venereal diseases have been completely revolutionized in these last twenty years. Gonorrhea is no longer thought of as a simple inflammation of mucous membrane, resembling a cold in the head and not apt to be any more harmful in its results. This mildest of the venereal diseases may invade any of the serous membranes of the body. The arthritis it sets up may cause ankylosis and permanent deformity. It may give rise to fatal peritonitis, or to crippling and at times mortal endocarditis or pericarditis. Its curability is one of the most uncertain things in medicine. It has been known to continue and prove infective fifteen years after the orignal acquirement although for many years it had been giving practically no symptoms. Such good conservative authorities as Professor Finger of Vienna and Professor Jullien of Paris, men of very large experience, absolutely forbid marriage for two years after an attack of gonorrhea.

So much for the milder venereal disease. Syphilis has always been a subject of very proper solicitude, but even its significance for evil has widened very much during the last quarter of a century. The direct effects of the disease upon the nervous system were scarcely more than suspected a few years ago. Now, they occupy a large place in pathology and the indirect effects of syphilis, the so-called parasyphilitic affections,

have become the most important part of neurology and syphilology. Practically all the apoplexies in patients under forty-five years of age are of syphilitic origin. Tabes, with its excruciating pain, its hopeless blindness, its crippling incoordination in the midst of torturing undisturbed mentality, is connected etiologically with syphilis in at least 70 per cent. of the cases.

The great mental disease of the century, general paralysis of the insane, is so closely connected with syphilis that there are good authorities who doubt if it ever occurs except in a patient with a syphilitic history. At the beginning of the century paresis was almost unknown. As the result of what Krafft-Ebing has strikingly called syphilization and civilization, the disease has become one of the most important in our modern insane asylums. Over 30 per cent. of the inmates of asylums on the Continent are general paretics. In England the proportion is scarcely less. In this country the average is well up to 20 per cent. of all the insane.

These are the facts in the matter of venereal diseases that have been acquired by recent medical investigations and observations. Although the general public is intensely interested in the subject, people have scarcely an inkling of these new points of medical knowledge. What must be begun at the present time is not a new vice-crusade, but an education crusade. Nothing is eventually more harmful to the cause of good morals than the spasmodic attacks of overzealous virtue, that attempts to reform the world all at once. Vice-crusades do more harm than good. If people can be impressed with the physical dangers inevitably associated with vice, then a public opinion will be created that will allow the enforcement of proper and systematic repressive regulations. At the present time legal regulation would soon resolve itself into nothing more than a new and powerful method of persecution and blackmail.

We must get beyond the mistaken notion that ignorance is innocence and that the subject of venereal disease must be tabooed. Our young men particularly must be given definite ideas as to the present position of medical thought in relation to the venereal diseases.

The German University method, by which lectures on the subject are delivered, not alone in the medical department, but to all the students of the University, is an excellent one. If in addition such lectures could be given at young men's clubs, great good would be accomplished and none of the harm that puritanic feeling imagines would result.

Here is the present duty of the medical profession for the prophylaxis of venereal diseases: Educate the people to right ideas. Just as education with regard to other contagious diseases has, not without delay and difficulty, produced a public opinion that now favors the enforcement of sanitary measures, even though individuals must suffer as a consequence, so, too, a public sentiment will be gradually raised up that will help and not hinder in the work of the elimination of the physical evils of venereal disease.

PATHOGENIC MICROBES IN MILK.

A tendency to the development of better dairy sanitation has been shown by the appearance of a number of articles during the last three or four years on the relations of milk to the spread of disease. Although belief in such a relationship is by no means new, the scientific consideration of the subject can hardly be said to have begun more than a dozen years ago. When one considers the important position which this article of human food occupies, especially in connection with the young in whom milk constitutes the chief nutriment, the need of investigation assumes clearer significance. In New York City alone it has been estimated that considerably more than seven million gallons of milk are consumed in a year. And, now that it has been incontestably established that milk may serve in the spread of disease-inciting micro-organisms, newer and more protecting measures should be enforced to ensure narrower limitation of this occurrence.

Milk as it exists in the udder of a healthy cow is practically germ-free, but it is a matter of common experience that all milk, however carefully it may be collected, however clean and aseptic may be the vessels into which it is received, will on standing, or after being submitted to the influences which are ordinarily at work between the time of collection and distribution, be found to teem with bacteria often of many kinds. For the most part, fortunately enough in this, the micro-organisms found are largely saprophytes. Of these, bacilli of the so-called colon and proteus groups are apparently the most common contaminations. It is to the rapid multiplication of one or the other of these that milk "goes bad." However normal in appearance, taste and chemical analysis, the milk as commonly distributed to consumers may contain hundreds of thousands of

bacteria per cubic millimeter. By their numbers and by their products of metabolism the common saprophytic species alone have often been shown to induce disease, especially in that fragile organism, the infant.

If the latter is true of milk containing, what has incorrectly been said to be, a normal flora, the gravity of the whole question is then further emphasized by the observations of various investigators who have repeatedly found pathogenic microbes in milk, such as is usually distributed for consumption. Among the diseases about which there is evidence showing that the exciting factor was transmitted through milk may be mentioned tuberculosis, scarlet and typhoid fevers, diphtheria, cholera, anthrax and several others.

The statements of various observers as to the frequency of the tubercle bacillus in milk are often divergent; thus the percentages given vary from 14 to over 60 per cent. Whilst Obermuller found that 61 per cent. of the Berlin milk tested contained tubercle bacilli, later investigations show that the percentage is usually considerably lower. Rabinowitsch and Klemperer (*Ztsch. f. Hygiene,* 1899, p. 137) more recently found only 28 per cent. of their samples of the Berlin milk to be similarly contaminated. In Liverpool and Manchester, in England, tubercle bacilli were found only in 2.8 per cent. in samples collected in the first-named city, and in 5.55 per cent. in those of the last-named city (*Lancet,* Jan. 20, 1900). On the other hand, milk collected from 16 Cambridgeshire dairies by Kanthack and Sladen contained them in over 56 per cent. of the samples (*Lancet,* Jan. 14, 1899). Just recently, Klein (*Journal of Hygiene,* Jan., 1901) demonstrated tubercle bacilli in 7 per cent. of the samples of "country milk" examined.

In almost all of these investigations the milk probably was obtained from cows with udder tuberculosis; for the experimental researches of the Royal Commission on Tuberculosis tend to show that the udder must be tuberculous before the milk becomes infectious.

There is one extremely interesting point in connection with the results of comparative tests of the sediment and cream of the same samples of milk; Kanthack and Sladen found that the cream was ordinarily considerably more infective than the sediment. An explanation of this is probably found in the studies of Freeman (*Arch. of Pedriatrics,* 1899), who found that as the cream rises to the surface it carries with it more than 90 per cent. of the contained bacteria, leaving the milk relatively free from micro-organisms.

In the case of typhoid fever and scarlet fever the demonstration of the relationship of milk to disease is largely based on circumstantial evidence; as yet bacterial proofs are still wanting. Notwithstanding, the proofs are convincing enough, as any one will find who takes the trouble to go over carefully the facts relating to various epidemics for which the milk has been held responsible. As far as diphtheria is concerned the evidence is complete; diphtheria bacilli have been found in milk. Thus Klein found this organism once in 100 specimens taken at random. That cholera may be spread by milk we have every reason to believe. Gaffky, who has written on cholera in Egypt and India, states that it is not infrequently a means of dissemination. An epidemic of cholera on ship-board reported by Simpson in 1887 is conclusive in this respect.

Fortunately, through the stimulating influence and energy of a small group of scientific investigations of milk in its hygienic applications, some of the larger dairies of the country have already taken important steps toward the realization of a safe and clean milk; those who have not yet taken precautions to safeguard the public health in this connection should be compelled to do so to the fullest measure by adequate laws.

THE TESTIMONY OF THE INSANE.

It is a part of newspaper effect to collect the opinions of eminent men on a certain subject and set them side by side for the public to compare. The recent discussions on the value of the testimony of insane patients, in criminal or civil suits, apropos of the trial of the Bellevue nurse, Davis, for manslaughter, have elicited a very interesting conflict of sentiment between physicians and lawyers.

It is instructive to note that the doctors agree. Several well-known alienists state that they consider it unwise to admit the testimony of any insane person. The lawyers, however, quoting precedent, hold that a witness need not be excluded from giving testimony because he is insane on some one subject. The case that established this precedent occurred just half a century ago. It was very similar to the one now under discussion. The man who was killed and the witness were both lunatic patients, in an asylum, and both slept in the same ward. The testimony

of the lunatic was accepted. The ruling of the Supreme Court of the United States in 1882, in a case where an insane man gave testimony, was that though a lunatic might seldom be a competent witness, yet the existence of partial insanity would not prevent him from giving accurate and lucid statements of what he had seen and heard; and that if he was capable of understanding the nature of an oath, and of giving a correct account of things he had witnessed, his testimony might be accepted. The question of the competency or incompetency of the individual was, in the matter of insanity, to be left, like incompetency, for any other cause, to the judgment of the court.

The real question now before the alienist and lawyer of to-day is whether the precedents of fifty and nineteen years ago shall stand in the face of the revelation of modern science. The whole theory of insanity has been revolutionized during the last twenty-five years. The idea used to hold that a man might be insane in one respect only, but absolute, sound in every other matter, as a man who had lost one finger from a hand, might be perfectly strong and skilful with the others. But modern neurology has taught us that faculties are not lopped off like fingers; but that any sign of mental failing is a sign of general mental disease, which affects the whole mental attitude of the patient in the form of warped judgment.

An insane man may have correct perceptions of outward events, but his description of these cannot be relied on, because, by reason of his disease, he distorts the outer world into a phantasmagoria, harmonizing with his own morbid mood. Careful observations have endowed the experienced alienist with an insight into the mental conditions of the insane, so that he is able to detect a hundred vagaries allied to the apparent delusion of the individual, where the casual observer would see but one. Were such an experienced alienist always at the command of the court to say, without party bias or political intrigue whether or not a certain testimony might be accepted as trustworthy, it would be possible to permit the exception to the rule of excluding insane witnesses.

But as the members of the court would be quite unable to pass such judgment, owing to their lack of knowledge, we feel that our legal brethren should accept the combined warnings of the alienists, and never permit an insane person to act as a witness.

The fact that in the present case under discussion, one witness was a paranoiac, is enough to make the idea of his acting as a witness impossible. But perhaps the members of the legal profession who know their precedent so well, do not realize that a paranoiac's ideas of his relation to his fellowmen are wholly distorted, that he is always abused, and has a perpetual "grouch" that is open to any one's suggestion. The other witness in the case was a patient with general paresis, which for the lawyer's benefit should be translated general decay.

If the court casts out the testimony of those whose moral character and past reputation shows them guilty of wilful misrepresentation, it should be equally chary of accepting testimony from those whose mental characteristics have proved them incapable of perceiving facts as they are.

THE CITY OF ORANGE AND ITS SMALLPOX HOSPITAL.

We hope that the bomerang of ignorance will not fly back at the citizens of Orange who have so foolishly demolished the temporary smallpox hospital that was put up for the care of patients who are now lying ill in a densely crowded part of the town.

Burning was the method that these enterprising citizens decided on as a means of abolishing the nuisance, but the Health Board, under whose care the hospital was being erected, stopped this enterprise and had the building patroled. But a mob armed with axes, spikes and crow-bars, in true revolutionary fashion, proved too much for the guards and succeeded in the work of demolition:

In the meantime the number of cases of smallpox is in danger of increasing. The crowded quarters of the tenement districts in which they are most numerous may have to be quarantined and these enterprising citizens may find themselves in closer contact with the disease than they would relish. The obstinacy of ignorance and the density of the fool alike furnish food for reflection.

ECHOES AND NEWS.

NEW YORK.

Bellevue Maternity Hospital.—The Medical College and Dispensary building of the Bellevue Hospital group will be altered from plans by Horgan & Slattery into a maternity hospital dispensary and dormitory. The changes,

which will be to the interior of the building, have been estimated to cost $20,000.

Gift to the Academy of Medicine.—The Academy of Medicine will get the medical library of the late Dr. Abbott Hodgman by his will, filed for probate last week.

Hospital Nurses' Home.—Plans were filed at the Building Department last week for the new nurses' home, to be erected for the Presbyterian Hospital at 31 to 37 East Seventy-first Street, opposite the hospital buildings. The structure, which has been designed by Architect James B. Baker, will be eight stories in height, and will occupy a plot 124 by 102 feet. Several months ago a benefactor, whose name was not disclosed, gave the hospital $300,000 for the erection of this home, provided the institution would assume the maintenance of it. Alexander Maitland, Secretary of the Board of Trustees of the hospital, said yesterday that the erection of the home would be a two-fold benefit. It would afford adequate living apartments for the nurses and give additional space in the buildings now given up to the medical and surgical wards, the top floors of which structures have heretofore been occupied by the nurses. According to the last annual report of the hospital, its corps of nurses numbers eighty-five.

How One Doctor Does It.—The persistence of a New York physician in his efforts to build up his practice might cause the County Medical Society to drop him if he happened to be a member and a case could be made out against him, says the *Sun*. He does not advertise. He writes letters. For instance, W. T. Smith, of 1213 West Twenty-third street, will find in his mail a letter addressed to W. W. Smith at his address. It is from this physician. In this letter he thanks W. W. Smith for his appreciation of the physician's skill and then outlines his case. The complaint described is usually one of the common ailments like rheumatism or dyspepsia or lung trouble. The doctor tells W. W. Smith that he has discovered an absolute cure for this disease and that his success in the Smith case was due to that. He concludes by asking W. W. Smith to come in and see him within a month that he may be sure his case is cured. W. T. Smith, who reads the letter, assumes that it was sent to him by mistake. If he happens to have symptoms like those described as W. W. Smith's and if he is as credulous of sure cure as most people are, he may call on the physician for treatment. There is no way to prove that the physician purposely misdirects these letters. He has been engaged in this sort of business for at least two years, however, and although these fake letters would seem to be forlorn hopes, they evidently bring results or he would discontinue them.

Appointment of St. Luke's Graduate.—Jonathan M. Wainwright, M.D., formerly house surgeon at St. Luke's Hospital, New York, has been appointed Surgeon-in-Chief to the Moses Taylor Hospital at Scranton, Pa.

Railway Surgery.—A joint session of the Section on Railway Surgery, with the Medico-Legal Society of New York, will be held on Monday, April 15, 1901, in New York City, under the chairmanship of Dr. Charles K. Cole, of Helena, Mont.

Prevalence of Grip.—The State Board of Health has issued a statement relative to the prevalence of grip in this State. The disease made its appearance in 1889. Every year since in the winter season it has recurred, the annual epidemic having various characteristics. The number of deaths which occurred each year from the disease is as follows: 1890, 5,000; 1891, 8,000; 1892, 8,000; 1893, 6,000; 1894, 3,000; 1895, 5,000; 1896, 2,750; 1897, 3,000; 1898, 2,500; 1899, 7,000, and 1900, 11,500. The statement says: "Of the distribution of the disease, it has not been found to be one of either the city or the country. It is a disease of the colder months. It has varied greatly in severity in different years; it seems likewise to have varied greatly in virulence in different localities and shown varying types. It likewise varies in rapidity of spread. It is evidently communicable from the individual directly and conveyable in infected clothing. Like all zymotic diseases, susceptibility to it varies; unlike some, immunity does not follow a previous attack. The State is now in the course of the twelfth recurrence of grip. Affecting the mortality of December by about 500, it has increased the numbers of deaths in January by probably 3,000, and was still in progress during February."

New York's Hospital for Insane and Narcomanias.—Assemblyman Henry last week introduced a bill providing for the establishment of a hospital in New York City for the special treatment of acute nervous and mental diseases. The city is to appropriate $250,000 for the maintenance of the hospital and the building is to cost $300,000. The board of managers is to consist of twelve members, six of whom are to be practising physicians. The physicians appointed as managers are to be the consulting and attending physicians of the hospital and shall have the care and treatment of all patients. A superintendent is to be appointed at a salary not exceeding $10,000. He is to be a physician of more than six years' experience and recognized as a specialist in neurology and psychiatry. He is to employ such attendants and nurses as he deems necessary. The object of the hospital is to prevent the removal of patients suffering from mental disorders to Bellevue, and all persons suffering from acute nervousness and mental diseases, who are residents of New York City, are to be received at this institution and detained there for a period not exceeding ten

days. Magistrates may commit persons to the hospital who appear nervously or mentally deranged until their normal condition may be ascertained. Persons whose sanity is in doubt can be confined there pending the determination of their mental condition. This is to prevent them being railroaded to an insane asylum. All cases of alcoholism, narcomania or habit neurosis may be committed to the new institution. The board of managers is empowered to dismiss patients committed to the hospital.

New York Skin and Cancer Hospital.—The New York Institute of Stomatology invites the profession to a special clinical lecture upon syphilis of the mouth and throat, to be given in the Hospital on Thursday, March 28th, at 4:15 P.M., by D. Bryson Delavan, M.D.

New York Academy of Medicine.—At the regular meeting to be held Thursday, March 21st, there will be held a symposium on the Present Treatment of Gonorrhea and Its Complications and Sequelæ." The following papers will be presented: (1) Acute Gonorrhea, by Dr. G. K. Swinburne; (2) Chronic Gonorrhea, by Dr. John Van der Poel; (3) The Complications of the Anterior Urethra, by Dr. M. I. Echeverria; (4) The Complications of the Posterior Urethra, by Dr. J. Pedersen; (5) Gonorrheal Conjunctivitis, by Dr. W. A. Holden; (6) Gonorrheal Strictures, by Dr. I. R. Hayden. Discussions by Drs. R. W. Taylor, Guiteras, Bierhoff, Lapowski, Fuller, Hill, Gibson, Chetwood and others.

PHILADELPHIA.

University of Pennsylvania Medical Bulletin.—We note that the change in the *University Medical Magazine*, which were announced in February, appear with the March issue. The title has been changed to read *University of Pennsylvania Medical Bulletin.* The reading matter is printed in double instead of single column, and advertising matter has been excluded. The policy and scope of the publication are in no way affected by these changes as it still continues to be the official organ of the Medical Department of the University of Pennsylvania. In its present form the publication is both attractive and dignified in appearance.

Increase in Typhoid Fever.—During the week ending March 9, 86 cases of typhoid fever were reported, against 18 for the preceding week. No cause for this increase, other that the low condition of the Schuylkill River, due to drought throughout the valley, is apparent. The report of the Bureau of Health for 1900, states that bacterial examination of milk taken from typhoid-infected houses failed in every instance to show the presence of typhoid bacilli.

Obituary.—Dr. Emil Schnizler died at his home in this city, March 6, of pneumonia. Dr. Schnizler was born in Germany sixty years ago, received his medical education at Heidelberg University, and was for fifteen years connected with the Vienna Hospital. While there he made special studies regarding the nature of rheumatism. Since coming to this city, twelve years ago, he had made a specialty of rheumatism, gout and neuralgic manifestations.

Streptococcus in Gynecology.—Dr. Guy L. Hunner, of Johns Hopkins Hospital, addressed the Obstetrical Society on the above subject March 7th. Mistakes in diagnosing this infection are considered inexcusable. The history of the case, in nearly every instance the infection following confinement, is of the greatest value in diagnosis. Localized abscesses should be opened through the vagina or by an inguinal incision, every effort being made to avoid opening the peritoneal cavity. Antistreptococcic serum has been used at Johns Hopkins, but is not considered of much value.

Libraries and Contagious Diseases.—The Board of Health at the last monthly meeting took the following action toward preventing the spread of contagious diseases: *"Resolved,* That the assistant medical inspectors be directed to obtain a list of the several public libraries in their respective districts and to furnish the Board of Health with a list of the same, and that the several libraries be furnished daily a list of cases of contagious diseases in order that books may be refused such houses in which contagious diseases exist."

Surgical Shock and Collapse.—Dr. Geo. W. Crile, of Cleveland, Ohio, by invitation read a paper on "Experimental Research into Surgical Shock and Collapse" before the College of Physicians March 6th. The reports of experiments on 250 animals, mostly dogs, were given. The animals were reduced to surgical anesthesia and killed before consciousness was regained. The effects on blood-pressure and respiration by cutting, crushing, or burning the various tissues of the body were ascertained. Traumatism on bone, cartilage, tendons, and fascia produced but little effect. Wounding of the nerve-trunks of the somatic area produced very marked effects, there being an immediate rise in blood-pressure. In amputations and disarticulations the principal change was caused by the division of skin, muscles, and nerves, and but little when the bone was sawn, or the joint opened. This result is contrary to old beliefs. Cutting or crushing the tongue had but slight effect. Drawing it forcibly forward and to one side sometimes caused total inhibition of the heart or respiration. This has an important bearing on the swabbing of the throat and consequent pulling out of the tongue by vigorous anesthetizers. Foreign bodies thrust in the pharynx and larynx caused marked inhibition and collapse in some instances. Positive in-

flation of the lungs may stop the circulation. Operations on the genitals showed opposite results in the sexes, a marked fall of blood-pressure being caused by crushing the testicles while in the case of the ovaries a rise was always produced. Experiments with blows on the pit of the stomach showed that no amount of manipulation of the solar plexus could cause collapse, the result in such cases being due to the effect on the heart. The conclusion reached was that shock is due primarily to impairment of the vasomotor nervous system as there can be no shock unless there be low blood-pressure. No fall in blood-pressure is caused by hemorrhage up to a certain point, but there is a diminished stock of reserve power and as a consequence shock comes on more easily after hemorrhage. After abdominal operations the continuance of shock depends on the amount of raw surfaces left, the tension of stitches, presence of blood-clots, etc. These factors help determine why one operator's patients recover more rapidly than do those of another. The statement was made that in cases of quick drowning death was caused by blocking of the circulation instead of by asphyxia.

Milk Inspection Inadequate.—The laws regulating the inspection of milk in Philadelphia and other cities of the State met with severe criticism from the members of the Pennsylvania State Veterinary Medical Association, which held its annual meeting here during the past week. Considerable time was devoted to the consideration of the inspection of milk and meat. Dr. Jacob Helmer of Scranton read a paper on "The Problem of Municipal Milk Inspection" in which he stated that the laws of Pennsylvania are markedly inadequate to the needs of the people. State legislation practically gives no authority to Boards of Health and Councils further than the appointment of an inspector to manipulate and analyze samples of milk. Competent inspection must include not only this, but the inspection of every cow of every dairy and the careful study and enforcement of dairy sanitation.

CHICAGO.

Medical College Gift.—The sum of $1,000,000 has been given to the Dunham Medical College by John E. Du Bois of Du Bois, Pa. The gift, so the officials of Dunham College assert, comes as an unsolicited testimonial for the benefits which his wife received recently in treatment by members of the faculty last fall. Mr. Du Bois is a multi-millionaire lumberman and mine owner. According to the announcement made to-day he makes this gift without any reservation, simply declaring that the money is at the disposal of the college authorities as soon as they have laid their plans for its disposition.

The Demands of Sanitary Science.—At a meeting of the Chicago Medical Society, held March 6th, Dr. H. M. Bracken, of St.Paul, Secretary of the Minnesota State Board of Health, read a paper on this subject, in which he discussed at considerable length the suppression of nuisances. A nuisance was defined as some feature objectionable to the sense of sight, smell or hearing, or a menace to health. The disposal of refuse taxes the ability of the sanitarian according to the varying conditions present in large and small cities. Refuse includes street-sweepings, various cast-off articles of clothing or factory, kitchen garbage, manure, dead animals, ashes, etc. Kitchen garbage has a food value in the feeding of hogs and any city with a population not exceeding 300,000, and surrounded by an open country, should find but little if any trouble in disposing of such material at comparatively little expense. It may be necessary under certain conditions to dispose of it by means of cremation, but this, as a rule, is a wasteful method and expensive, and is to be avoided when possible.

School Inspection and Infectious Diseases.—As to the control of the spread of infectious diseases, probably there is nothing that will accomplish more than a thorough system of school inspection. School inspection does not cover the entire problem of proper sanitation for schools, for the proper ventilation, heating, and lighting of school buildings, together with an insistence upon the individual cleanliness of pupils, places a great responsibility upon architects which too often is not recognized.

State Aid in the Prevention of Tuberculosis.—Dr. Charles O. Probst, Secretary of the State Board of Health of Ohio, read a paper with this title. He presented an argument in favor of the following propositions: (1) The State should provide hospitals for the reception of persons suffering from tuberculosis, and should assist municipalities or counties to construct similar institutions. (2) Physical education, conducted by trained medical men, should be made a part of the common-school course; and students in normal schools, colleges and universities should be instructed in hygiene, including a proper knowledge of the causes and prevention of tuberculosis. (3) The State should exercise a much closer supervision over the construction, ventilation and care of workshops and factories, especially where the occupation is conducive to tuberculosis. (4) The State should prohibit the sale of milk from tuberculous animals, and should provide for the inspection of dairy cattle. It should enforce the proper stabling and care of such animals. The essayist urged the erection of a hospital for consumptives by the State for the treatment of carefully selected cases. It would seem to be wise, at least in the beginning, that the patients should pay the greater part of the operating expenses. The charge of

$5.00 a week, established for the new Massachusetts hospital, appears to be a reasonable one. Hospitals more strictly for the prevention of tuberculosis should be established by municipalities, or possibly by counties. The aim here should be to select and isolate those cases which are the greatest danger to the public. Such cases are usually found among the unfortunate, poorest classes. Many of these find their way into general hospitals or have to be treated in their homes at public expense. He urged the physical education of school children, with the teaching of hygiene and the cause and prevention of consumption to students in advanced institutions of learning.

Miscarriage of Municipal Sanitation.—A paper with this title was read by Dr. Ernest Wende, Health Commissioner of Buffalo. The following is a summary of his paper: There should be (1) unity of law, procedure and action throughout the State in regard to contagious diseases, even further in this relation, throughout the States, interstate contagious disease laws. (2) Interstate law covering contagious diseases in animals, particularly tuberculosis. There seems every reason for believing that the pathology of the superior animal —man—would be benefited by such legislation. (3) The vesting of city health officials with certain State Board of Health inspection powers, to permit them, under certain circumstances, to extend their action beyond the municipal confines. (4) Municipal sanitation and State medicine to be made a more important feature in education, particularly in universities. It should be made contingent that health officers qualify by such course of study before being eligible. (5) Requirements of sanitary education everywhere; in the public schools, in the high schools, colleges and universities, so that by the time the younger generations mature, enlightenment will have reached our various legislative bodies. (6) Selection of municipal health officers for their fitness, with secure tenure of office, and proper compensation. The municipality should not be exposed to an unnecessary risk by politics.

Bill Amending Inheritance Tax Law.—Senator Bussey has introduced a bill amending the inheritance tax law by providing that when beneficial interest passes to a hospital or other charitable institution, it shall not be subject to tax, but that the exemption shall not apply to institutions which are operated for the profit of its owners.

Appointment of Dr. Schaefer.—Dr. Frederick C. Schaefer has been appointed gynecologist to St. Elizabeth's Hospital and Surgeon-in-Chief to St. Hedwig's Hospital.

GENERAL.

Iowa State University Loss.—With wind blowing at the rate of fifty miles an hour, fire broke out March 11th in the Medical Building of the State University, and forty minutes later it was a mass of ruins. South Building, one of the oldest in the State, caught fire later, and is also a total loss. There is no insurance, and the loss will reach upwards of $250,000.

Grave of Hippocrates Found.—A despatch to the London *Chronicle* from Vienna states on the authority of a telegram from Athens that the grave of Hippocrates was discovered during excavations at Larissa. A royal commission was immediately sent to verify the report.

Medical Library for the Oranges.—The medical and surgical library of the late Dr. William Pierson, of Orange, numbering 2,000 volumes, has been presented by Mrs. Pierson to the physicians of the Oranges and they have decided to organize the William Pierson Medical Library Association. Ultimately, it is expected, this will result in an Orange academy of medicine, with a building for the library, rooms for meetings of the local medical societies, lecture halls and probably courses of instruction on medical topics. For the present the library will be placed in the Stickler Memorial Library. The Stickler Library is now building as a memorial to the late Dr. Joseph William Stickler and his extensive medical library is also to be placed in the building. Physicians have named a committee to prepare a plan of organization which will be adopted at a meeting to be held soon.

University of Michigan.—Mrs. Love M. Palmer, widow of Dr. A. B. Palmer, who was Professor in the Medical Department of the University of Michigan from 1852 up to the time of his death, fifteen years ago, died March 9th. By the terms of her will, she leaves $85,000 to the University. It is understood that $20,000 will go to build a new ward for the hospital, and $15,000 to maintain free beds in that institution.

Monument to Dr. Ollier.—The undersigned constitute a Committee similar to those formed in several European countries for the purpose of receiving subscriptions for a monument commemorative of the distinguished scientific services of Professor Leopold Ollier. Among the members of these Committees are Lord Lister, Professors von Bergmann, Czerny, Durante and other leading men. The municipality of the city of Lyons has dedicated an open space adjacent to quarters of the various academic faculties on the border of the Rhône named in is honor "Place Leopold Ollier." The profession of this country is well aware of the great services rendered by Professor Ollier, especially in the domain of plastic and osseous surgery. His labors have been most fruitful in the domains of surgery, of physiology and of pathology. The committee hopes to raise not less than one thousand ($1,000) as a testimonial from the profession of America. Checks should be forwarded to W. W. Keen, M.D., 1729 Chestnut St., Phila-

delphia, Pa., and at as early a date as possible. *Committee:* Robert Abbe, New York; William T. Bull, New York; P. S. Conner, Cincinnati; A. T. Cabot, Boston; Howard A. Kelly, Baltimore; W. W. Keen, Philadelphia; Rudolph Matas, New Orleans; Wm. J. Mayo, Rochester; W. F. McNutt, San Francisco; Roswell Park, Buffalo; Clayton Parkhill, Denver; Maurice H. Richardson, Boston; Nicholas Senn, Chicago.

Obituary.—Dr. William Dexter Anderson, a well-known physician of New Haven, died last week as the result of an operation for intestinal trouble. He was born in Londonderry, N. H., sixty years ago, and was graduated from the Yale academic department in 1862, and from the Yale medical school in 1865. He was a musical composer of some note in his early days, but never had any of his works published.

King of England's Appointments.—King Edward VII. has appointed Lord Lister to be Sergeant-Surgeon in Ordinary and Sir William MacCormac and Sir Thomas Smith to be Honorary-Sergeant-Surgeons. Honorary Physicians to the King, Dugal McEwen, M.D.; Sir James Dennet, Inspector-General of Hospitals and Fleets; Sir John Watt Reid, Director-General of the Medical Department of the Navy (retired); Adam B. Messer, M.D., Inspector of Hospitals and Fleets; Henry C. Woods, M.D., Inspector-General of Hospitals and Fleets (extra). Honorary Surgeons to the King: Sir James Jenkins, Inspector-General of Hospitals and Fleets; Timotheus J. Haran, Inspector-General of Hospitals and Fleets; Sir James N. Dick, Director-General of the Medical Department of the Navy; William H. Lloyd, Inspector General of Hospitals and Fleets; Alfred G. Delmage, Deputy Inspector-General of Hospitals and Fleets.

Anniversary of Dr. Hansen.—Dr. G. A. Hansen, the discoverer of the lepra bacillus, will celebrate his sixtieth birthday, July 29, 1901. It is proposed to erect to him a marble-bust in the Bergen Hospital (Lungengaard) where he has worked so many years and in whose laboratory the life history of the bacillus was worked out.

CORRESPONDENCE.

THE OPIUM HABIT.

To the Editor of the Medical News:

Dear Sir: I have never lived in India, like Kipling, nor in China, like Dr. Wm. Hector Park of McMeekin, Fla., but, as a resident of New York and as a close observer for a quarter of a century of the opium addiction as practised in all its forms by the lowest type of Mongolian as well as the highest physical and intellectual type of the Caucasian, I can affirm that, no matter where the question may be studied, it is one that should be based on personal, practical knowledge. One should look into the matter with a full appreciation of all its phases, good, bad and indifferent, as they may be.

It is more apt to prove satisfactory in dealing with a sociological problem to begin by understanding one's own place in one's most natural environment before studying a foreign being in his habitat, viewed by prejudiced eyes. A question of toxic drug-action is one that can be studied as well in civilized communities, among English-speaking, or intelligent races, as by trying to observe this phenomenon upon utterly alien peoples in their own peculiar and unfamiliar environment.

It sums itself up in the fact that to really understand the question of the opium habit in either its sociological, economic, ethical or medical aspects, it is not necessary to go to India, China, Japan or even to San Francisco. Right here in New York City one can see and study all the phases of the subject and New York presents, it would seem to me, on account of its cosmopolitan population, as fertile a field for investigation of this interesting subject as India or China, especially as it does not present sociological difficulties of language and many other features that would handicap one in becoming personally acquainted and in touch with the subject.

New York undoubtedly contains thousands of opium habitués, varying widely in the peculiar form in which they take the drug. The Mongolians, for the most part, seem to be habitués of the pipe, and they are to a great extent *limited* smokers, confining themselves to a minimum amount of the drug and using it much as the holiday drinker of alcohol. It is the Chinaman's "off-day" pleasure, a sort of Saturday and Sunday recreation. He seems very moderate in his requirements and nothing is ever thought of this moderation as but the usual thing, emanating from the customs of his country. The Chinaman of New York is an industrious, hard-working man, and the few glaring exceptions of the opium fiend in all its horrors do not apply to his class, unless it be in the sick or the exceptionally "bad" Chinaman.

My experience has taught me that the majority of the pipe-smokers among the Chinese are limited smokers and are absolutely unharmed by their practice.

In the case of the white race it is different, but only to a slight degree. All who seem to become absolute slaves to the various opium addictions are, as a rule, of a peculiar perverted type. The drug does not altogether psychologically and physically change the individual. It seems to fit *his type of character.* It is not so much that one can see the opium *facies* and character and recognize them readily, but one can also recognize a singular type of man and woman whom one would unhesi-

tatingly classify as addicted to some habit or who is perverted mentally, morally, or physically. This class is seen among our anemic cigarette fiends, who have all the peculiar general aspects of the opium fiend.

There are great differences in the general actions and habits of the "fiend," whether he is addicted to morphine by the mouth, or is the user of the hypodermic or the devotée of the pipe. There is a vast chasm between the morphine fiend and the smoker which is difficult to bridge. He who indulges in the "gun" is further away still. He neither cares to indulge in the simple pleasures of the pipe, nor does he contemplate the possibility of the satisfaction of content following a dose by the mouth.

There are many devious windings in the path before the fiend incarnate stage of the hypodermic is reached. There are thousands in New York City to-day who are satisfied with their daily smoke or a fraction of a grain of morphine as there are thousands upon thousands that are satisfied with their drink or two a day. The moderate opium addiction is not only a possibility, but it is a fact; a fact that is known to many, but the habit, or pleasure, is a more or less secret one on account of the opprobrium of the wise saws and moralists who write and control legislation on a subject they wot not of.

The opium habit is pernicious—it is bad and it is to be condemned in any country or in any man. This is all true, but it is in no way as pernicious, bad or unhealthy, from any standpoint, as alcohol. There are more drinkards made by the incessant demands upon the economy for more alcohol than there are "fiends" from the daily increasing psychical demands for the drug.

Pathological science teaches the practical fact that there is a far greater amount of actual modification of the body tissues, as a result of the use of alcohol than is possible to bring about by the use of opium or its derivatives. Alcohol changes the tissues directly; opium will not do so, except indirectly by its interference with tissue nutrition.

The opium habitué is only discovered by his admission or great excess. The alcoholic is vastly easier to discover. Mentally and physically the confirmed alcoholic is to be classified as a greater mental and physical departure from a given norm. To compare these again sociologically, the man who indulges in the public cup or the secret pill, one who really knows would unhesitatingly say that they are immeasurably far apart, and degradation sits with the followers of Bacchus and does not recline beneath the "shadow of the poppy."

To say that one cannot indulge in a modicum of opium daily for years and refrain from increasing his daily dose is to say what is untrue. Or to say that necessarily one neither obtains comfort nor pleasure therefrom and that misery and poverty sit at one's doorstep is also a fabrication.

The great trouble in the study of all types of habit neuroses or drug addictions is to obtain false impression from the extreme cases. To understand how impossible it is for the ordinary man to obtain important data upon a question of this kind is to realize the great difficulty in coming closely in touch with the secret devotée.

The intelligent man is not going to talk upon his habit. The ordinary individual will dilate upon the subject of alcohol; this is a subject which society permits to be discussed. How rare to find one who can talk intelligently on the subject of opium or understand it unless it is in a statistical, deprecatory manner as far away from any fact as the general tenor of Dr. Park's statements. To understand this subject it is not necessary to quote Kipling nor Dr. Parks, but to take up one's abiding-place among the people who use the drug. Then one soon will learn that there is a vast difference in the use and the abuse of this most useful of medicines to man, and it would not be long before one would be convinced that in no way nor from any standpoint is it as dangerous to the community as alcohol.

Charles H. Brown, M.D.

25 West 45th Street, New York, March, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 2, 1901.

MR. BURDETT-COUTTS' STRICTURES ON THE SOUTH AFRICAN HOSPITAL COMMISSION—BAD AMBULANCES AND OUT-OF-DATE TENTS—FEEDING OF TYPHOID AND DYSENTERIC PATIENTS ON BULLY-BEEF AND BISCUITS—PREVALENCE OF TYPHOID FEVER IN THE TROOPS; 19,000 CASES, OVER 4,000 DEATHS AND NEARLY 11,000 MEN INVALIDED—PLAGUE IN INDIA INCREASING—THE EPIDEMIC OF ARSENICAL POISONING; 36 DEATHS IN MANCHESTER—ARSENIC SUPPLIED TO THE SUGAR MANUFACTURERS AT THE RATE OF 4 TONS IN 30 WEEKS—PLAGUE AT THE CAPE—THE HUNTERIAN ORATION—THE FORM OF THE HUMAN SKULL AND THE ORIGIN OF MAN—THE ANTI-TUBERCULOSIS MOVEMENT—GREAT DIMINUTION IN THE DEATH-RATE FROM CONSUMPTION.

In Mr. Burdett-Coutts' second letter he passes from the defects of principle which he claims to have established in his first letter (described in my previous communication) to specific cases showing the grave defects of the Commission. So far no attempt has been made to answer his trenchant and grave indictment, although a few of the Conservative and, therefore, Government organs have in a

general way tried to depreciate his letters without answering his charges in any way. The Commission urges that duly qualified special sanitary officers should be forthcoming in future wars—a proposal which Sir Walter Foster, a medical member of Parliament, laid before the Government at the beginning of the war and which they, in their superior wisdom (!) rejected. Mr. Coutts asks, Would not the recommendations under this head have derived incalculable weight if the report had brought out a few of the grave results from their neglect? One case would have been sufficient, such as that of the 2nd Worcesters, who came fresh and healthy from Bermuda, marched over a clean trek into Bloemfontein with only two sick, were camped on ground just evacuated by a Paardeberg regiment, and within 3 weeks had 278 men down with typhoid fever from which 40 or 50 died. Then instead of sending out 8 or 10 consultants at a salary of £5,000 a year each, would it not have been better to have sent 20 or 30 experienced practitioners who could have taken charge of the larger hospitals? As to the ambulances the Commission fully supports Mr. Coutts' condemnation of the clumsy, inefficient vehicles in use. It also supports his criticism on the persistent use of the heavy marquee instead of the larger and far lighter tortoise tents used in all the private hospitals. But why are not the results of this mistake pointed out, *i.e.*, that the use of the marquee at places to which transport is the main difficulty restricts the tent accommodation for patients by nearly one-half? The Commission strongly supports his recommendation in favor of female nursing. It says, "Of course nurses could not be employed in field hospitals or at the front." But when a field hospital moves up to a large town on the rail and is stationary there for two months it could have nurses just as well as a general hospital. One of the greatest evils due to local mismanagement was the treatment of patients when being conveyed by train from the front to the base, a journey of three to five days, often performed in open trucks without extra clothing and in bitterly cold nights. The feeding of the patients who were mostly suffering from typhoid fever and dysentery on bully-beef and biscuits deserves the strongest censure. The Commission does not appear to have discovered how widely this practice prevailed. On the question of the high typhoid-fever mortality the Commission refuses to entertain a comparison between the private and military hospitals and then proceeds to accept such a comparison based on two military hospitals picked out by the principal officer of the Medical Corps. In the Volks private hospital at Bloemfontein the typhoid-fever mortality was 7.75 per cent.; in the military hospitals in the same town it was 21 per cent.

The serious mortality from typhoid fever in South Africa is shown by the following figures given by the Government in the House of Commons. In October there were 568 cases of typhoid fever and 98 deaths; in November, 1,213 cases and 207 deaths; in December, 1,665 cases and 286 deaths. The total number of cases from the beginning of the war up to December last was 19,101; total of number of deaths, 4,233. The number of men invalided with typhoid fever who have arrived in England is 10,975.

Plague in India is increasing. In the week ending January 17th in the whole of India there were 2,839 deaths compared with 2,463 in the previous week and 1,279 in the corresponding week of last year. There were 575 deaths in the Bombay Presidency, 1,863 in the Bengal Presidency, 37 in the Madras Presidency, 23 in Punjab, and 341 in the Mysore province. In Calcutta there were 78 new cases and 76 deaths. In Bombay city there were 293 deaths—a great increase. The total deaths were 1,119, equal to a rate of 68.97. Of this number 222 were due to plague—an increase of 68. A fifth outbreak is now developing and the disease is distributed over the city. Several dead bodies have been found in the public roads. The week ending January 24th shows a further increase of plague. In the whole of India there were 3,277 deaths.

The report of Dr. Buchanan, a medical inspector of the Local Government Board, to that body on the recent epidemic of arsenical poisoning has been issued. He has visited places known to be affected by the epidemic in Lancashire, Cheshire, Staffordshire, Worcestershire, Shropshire, Yorkshire, Nottinghamshire, Warwicksire, Northamptonshire and Leicestershire. He finds that there were in Manchester 2,000 sufferers from the epidemic, in Salford 782, in Chester 46, in Birkenhead 100, in Stowbridge 30, in Staffordshire 667. As to the mortality he says that without detailed knowledge it cannot be estimated. There were 36 fatal cases in Manchester between November 28, 1900, and January 10, 1901, 23 of the patients being women, and 13 men.

At the inquest on the body of a woman who is supposed to have died from arsenical poisoning in beer Dr. Campbell Brown, an analytical chemist associated with the Liverpool University College, stated that he had analyzed samples of sulphuric acid which had been supplied to Messrs. Bostock, manufacturers of brewers' sugar, and found that they contained on an average 2 per cent. of arsenic. The deliveries of sulphuric acid were at the rate of 7 to 8 tons a week. At this rate over four tons of arsenic would be supplied in thirty weeks, or 2,191,000 grains—enough to kill 1,000,000 people!

Mr. Edington, the Government bacteriologist, has discovered anthrax in the suspected cases of plague at Cape Town of which I have

informed you in my last letter. There are 12 undoubted cases of plague in hospitals and 4 doubtful ones. Two deaths have occurred, both victims being Kaffirs. There is only one white patient suffering from the disease in hospital. Twenty-four colored persons and 79 Kaffirs are in the "contact" camp. The authorities are redoubling their efforts to check the progress of the plague. The thousands of natives living in filthy hovels in the city are a source of great danger and the Government has decided to remove them to a location which is to be formed immediately on the Cape Flats.

The Hunterian oration at the Royal College of Surgeons, which was instituted to commemorate the work of John Hunter and his successors, was delivered by Mr. W. C. Macnamara, F.R.C.S., who took for his subject "The Form of the Human Skull and Its Relation to the Origin of Prehistoric Man in Western Europe." This subject there is reason to believe occupied the attention of John Hunter, the unrivalled collection of skulls in the museum of the College having been founded by him. From an analysis of the maximum number of anatomical characters common to man and anthropoid apes, it is proved that they are derived from the same stock. How has the difference arisen which exists between them as regards intellectual capacity? The body of an ape sometimes weighs more than that of man, but the brain is only half as heavy as that of an average European. The defect in the size of the ape's brain is most conspicuous in the anterior lobes. They have no speech center, consequently they cannot acquire speech. The defective anterior lobes of the ape are due to the small capacity of the skull caused by closure of the sutures, during the first year of life. An ape's brain, therefore, remains always an infantile brain; whereas in man the fore part of the skull does not consolidate until adult life and the speech center may continue to develop until the twentieth year. But this was not always true, for the human skull found in a tertiary formation in Java is clearly on the border line between man and apes and the skulls of the men living in Europe during the preglacial and interglacial periods resemble in form and structure more closely the crania of the chimpanzee than those of existing Europeans. In the post-glacial formations are skulls of the same type, but more highly developed. These post-glacial people were a short, powerful, long skulled race, the Africo-Europeans or Iberians who seem to have been the sole inhabitants of our continent at that period. Their stone, bone and horn instruments were superior to those of the glacial period. Their development is attributable to an alteration in the climate and fauna of Europe which compelled them in the struggle for existence to make greater use of their brains than their predecessors had. As their crania had innate power of growths their brains were able to respond to this call. As the neolithic period advanced the remains of a very different race are found in Western Europe. The men had large, well-formed skulls, possessed animals of an Asiatic stock, and used a language which still survives. They are believed to have been a branch of the Proto-Aryan race. Their remains are found in the Cro-Magnon and Mentone caves of France and in the long dolmens of England, Ireland, Europe, Asia, and North Africa. Then followed the bronze period when hordes of a short, small-boned, broad-skulled, Mongoloid race from the southeast of Asia passed into Europe bringing with them bronze instruments which gradually supplanted the stone and bone articles in use. They were the lake dwellers of Switzerland. In time they became absorbed into the pre-existing inhabitants and formed the ancient British stock. They were subdued by hordes of Teutons from Northern Europe and intermarried with a remnant of them, forming the Anglo-Saxon race. The existing European population is thus a mixed race. Nevertheless, from the measurement of the heads of 10,000,000 people it has been ascertained that in those countries which border the Mediterranean the people are still a short, dark, long-skulled race (Iberians). North Germany and Scandinavia contain a large proportion of the tall, fair, long-skulled Teutonic race (Aryan), and a vast triangle with its base in Eastern Russia and its apex in central France is inhabited by the descendants of the broad-skulled Mongoloid and Turanian races of central Europe. Environment acting for long periods on people of the same race has produced not only fixed hereditary physical character, but also specialized areas of nerve structure by means of which mental characteristics are transmitted as different as those of the Iberians of South America are from those of the Anglo-Saxons of the United States. Applying these principles to the vast and increasing populations of our towns Mr. Macnamara concluded that even in a few generations the people show indications of changes which will be more pronounced in their descendants. He is convinced that city children are deficient, as compared with country ones, in acuity of vision.

The anti-tuberculosis movement is still active. At Worcester a conference was convened by the County Council to hear addresses on the new method of treatment and to consider the best way of making it available for the poorer classes. The interest taken in the subject was shown by the large attendance, representing the County Council, the various local authorities, the medical profession, and some of the leading county families. Sir James Crichton Browne, who attended on behalf of the National Association for the Pre-

vention of Consumption, said that it was the work of Pasteur, followed by Lester, Koch and others, which made the present crusade possible. To stamp out tuberculosis might seem chimerical, but nevertheless that was the object of the National Association which was inaugurated two years ago. In 1838 out of every 10,000 persons in England and Wales 38 died of consumption, in 1899 only 13. The rate of diminution was a slightly increasing one and if maintained for another 30 years consumption will have entirely disappeared. The decline is traceable to subsoil drainage, sanitary reforms, increased cleanliness, and improved conditions of life generally. But the beneficent effects of these seem to be approaching a maximum, while overcrowding, one of the most prolific causes, seems likely to increase. The diminished death rate from all forms of tuberculosis means an annual saving of 75,000 lives. Promiscuous spitting should be prohibited for consumption might exist for a considerable time before it was detected. While pulmonary tuberculosis has been diminishing, intestinal tuberculosis, an affection chiefly of children, has been increasing. It is reasonable to connect this with tuberculosis milk. Private slaughter-houses should be abolished and municipal abbatoirs provided where all meat exposed for sale should be subject to inspection. Attention to cow-houses and dairies was of vital importance, infected animals should be separated from the rest of the herd and fattened for killing. Statistics of the open-air treatment are not available, but it seems clear that in the first stage of consumption 50 per cent. of radical cures and marked improvement in 25 per cent. can be obtained.

SKIAGRAPHY VERSUS THE PRACTITIONER—OVARIAN CYSTS—MECHANISM AND MANAGEMENT OF THE THIRD STAGE OF LABOR—AGGLUTINATION PHENOMENA—EXTENSIVE INTESTINAL RESECTIONS—INSTANTANEOUS RADIOGRAPHY.

W. H. Brown, at the Leeds and West Riding Medico-Chirurgical Society, January 11, 1901, discussed the skiagram and its relation to the practitioner, especially in a medico-legal sense. The time has passed when the public was satisfied whether or not a limb was useful and strong after fracture. The appearance of the skiagraph in the field and especially within the reach of the laity has been a dangerous factor for the reputation of physicians and surgeons and often not deservedly so at all. Very likely many suits have been unjustly brought and in some cases even without warrant, because the local savants have turned the X-ray machine upon a limb otherwise perfectly sound and serviceable, but with the bone not mathematically or esthetically straight. The practitioner can protect himself always in one of two ways, best by both. He should treat no fracture without the aid of a consultant and he should always take a skiagram before and after reduction in order to prove what has been accomplished by the setting.

F. W. N. Haultain, at the Edinburgh Obstetrical Society, January 9, 1901, read a paper on the intraperitoneal rupture of ovarian cysts. In the majority of cases beyond question the rupture occurred without the knowledge of the patient, unless the tumor had been so large as to have attracted attention. The reasons for this are that the peritoneal cavity is purely potential and the contact of this viscera with each other hinders rapid escape of the cyst-contents; and also that in most cases the evacuations are sterile and harmless. In those cases which are recorded the majority show severe or even fatal symptoms. Palm in a series of 18 cases mentions 3 deaths due to collapse, 6 to acute peritonitis, 6 to chronic peritonitis and 3 to continued fever. Nepleen in 155 cases shows 65. The causes of death were chiefly profound irritation by the cyst-contents, sepsis and hemorrhage. The causes of the rupture of the cyst are variously stated, violence, morbid cyst-wall, intracystic hemorrhage, thrombosis, and twisted pedicle. Commonest of all is the softening of the cyst-wall when the cyst-contents are gelatinous. Such jelly-like contents are very slowly absorbed, hence may distend the abdomen if originally copious or if their production continue for any reason and, therefore, are the form of abdominal contents usually discovered after such rupture. On the other hand, many cysts are filled with practically only normal salt solution, which is absorbed so rapidly that it causes temporary polyuria. Such cysts, especially those in the broad ligament, may undergo total obliteration, or secondary single or multiple cysts may and often do arise as is shown by the presence of cicatrices in the walls of those found *in situ* at operations. Rupture, with spontaneous evacuation, or operative tapping, if done long before the laparotomy, often produces peritonitis, through the irritative quality of the fluid, so widespread as to render subsequent removal of the cyst-wall impossible. The treatment consists in such cases of the removal of the cyst as soon after evacuation as possible, thereby avoiding the risk of adhesions inherent in delay. At the laparotomy the mere incision of the peritoneum might be followed by such a gush of fluid as to simulate opening of the cyst itself. Stripping of the parietal peritoneum might then be done on the supposition that the cyst-wall is being enucleated. To avoid such an error the incision should always admit the hand for thorough exploration. The symptoms of rupture of a cyst are often so acute as to simulate any of the acute surgical abdominal conditions, especially when no cyst or other pelvic tumor has been previously discovered. In such cases the operation is *per se* exploratory.

B. Hart discussed uterine retraction with spe-

cial reference to the management of the third stage of labor and its mechanism. There are discrepancies between the theories of the mechanism of the third stage and the practice of its management. Retraction he defined as a distinct muscular action (a contraction) in which some of the thickening of the uterine muscle was maintained after the real contracting force had been expended. At autopsy postpartum normal uteri all seem to show the wall thinner at the placental site than elsewhere. Uteri removed during the Porro operation have uniformly thick walls, probably because of the stimulus of the longitudinal and transverse incisions. Uteri taken from the body after death, intact with the placenta *in situ*, always show a thinning of the muscle over its attachment, which is indeed thinner than anywhere else above the retraction ring. He next emphasized the importance of the elastic recoil of the womb produced no doubt by the large amount of elastic tissue in its walls. Such recoil occurs after each pain during the period of repose. The final point is that the placenta separates by a disproportion between this recoil as it occurs in the placental area and elsewhere. Hence, before such separation has really occurred the Credé method of expulsion is dangerous.

F. W. Andrews and H. A. Schoelberg, at the Pathological Society of London, February 5, 1901, gave a preliminary report of the results of their experiments as to the relative agglutination phenomena, seen after immunization against the bacillus typhosus and its allies. Andrews pointed out the importance of observing and recording the *quantitative* factor in all these cases. The degree of dilution at which a given serum will produce clumping has an important bearing on the diagnosis. Experimental immunization against the various members of the group of bacteria of which the bacillus typhosus is a member offer the best means of observations. The questions attacked were: (1) Does the poison exist as a soluble entity which may be filtered off from the medium in which the germs have grown, or as a constituent of the cell-protoplasm of the bacterium itself? (2) Is the reaction of agglutination evoked by a product common to all the members of the group or peculiar to each species alone? Klein and others have already shown that several species possess a common poisonous product and that each also produces its particular toxin. In their experiments, carried on chiefly by Schölberg, the aim was to reach as accurate an estimate as possible of the *quantitive* factor in these cases. The point determined was the limit of dilution at which a given serum will produce agglutination in a definite time (one hour) in emulsions of living organisms prepared from fresh gelatin cultures of them. The results of the experiments so far as they have been completed are as follows: (1) The product which is responsible for the agglutination resides in the cell-protoplasm, rather than in the soluble toxins themselves. (2) A share in the process is borne by a product in common to all the bacteria of a given group. For example, the serum of an animal immunized against the bacillus typhosus and producing active agglutination of it will to a lesser degree excite clumping of the bacillus coli communis and of the bacillus of Gärtner. (3) In addition there is an element present in each species by itself which excites a higher degree of agglutination upon that same species. (4) The rabbit is a more suitable animal than the guinea-pig for these experiments, because it produces serum of higher agglutinating power. Schölberg then described in fuller detail the methods adopted in the experiments and the precautions taken to avoid mistakes and fallacies. The toxins were obtained from the usual broth cultures after they were three months old, and proved to be sterile by cultivations made, repeated, and found consistently sterile. The bacterial injections were made from bacteria grown on dry agar entirely free from the water of expression. Suspension of a variable amount of agar culture was made in sterile normal saline solution and heated to 70° C. for sixteen minutes. Cultivations made from the bacteria injected were sterile. Broth cultures were not used in making the emulsions for agglutination tests, because they are not reliable. Gelatin cultures from forty-eight to one hundred and twenty hours old were used in the emulsions with sterile normal salt solution. Carefully plotted charts were prepared for comparison and exhibited. The first agglutination experiment was done on the fifth or sixth day after inoculation with Prof. Wright's sterilized broth cultures, bacillus coli and Gärtner's appearing one day later as the bacillus typhosus rose. The coli and Gärtner curves ran together, but independently of the typhoid. Inoculation of animals with pure typhoid toxin gave an average maximum dilution of 1 to 40 for typhoid; the coli and Gärtner were entirely negative at that index. On one occasion only when the typhoid index was 1 in 100 did the other two agglutinate and then after dilution of 1 in 10. Using the bacteria only in the rabbit, agglutination occurred on the fifth day for typhoid and on the sixth day for the Gärtner and the coli. A maximum dilution of 1 in 500 for the typhoid was represented by 1-50 for the other two on the ninth day. Using guinea-pigs the reaction was not so active and showed that when Gärtner's bacillus was inoculated the reaction for the typhoid and coli were negative, although for the Gärtner it was present at a dilution of 1 in 130.

T. Myles, at the Royal Academy of Medicine in Ireland, December 7, 1900, presented a paper on the removal of large sections of the intestine in man and animals. One of his patients was brought before the meeting. The ten-year-old boy was run over by a truck carrying a ton and a half of grain over the mid-lumbar region while lying upon his stomach. This great traumatism produced no fracture of the vertebræ and very little external evidence of its presence. Seventeen hours after it a laparotomy revealed extensive damage to the intestine and a long trans-

verse rent in the mesentery. The length of intestine resected measured eight feet four and a half inches. The patient made an excellent recovery. His present condition is merely that of looseness of the bowels and an abnormally large appetite. The balance of his paper concerned the results of experiments on animals and an analysis of thirty-three cases in which over three feet had been removed in man. The conclusions are from these cases that when less than six feet six and a half inches are removed the intestinal symptoms are, as a rule, wanting, but present when more than this length is taken. Children seem to bear these extensive removals better than do adults, just as they often do other interferences.

E. W. Shenton, at the Clinical Society of London, February 8, 1900, discussed instantaneous radiography, by which is meant the reduction of the exposure to reasonable limits, from one to thirty seconds. This can be accomplished by using larger and stronger tubes, which will not only shorten the time, but actually increase the penetration, revealing deeper parts of the body. Such are very valuable for detecting foreign bodies and especially for renal calculi. The writer has found a very simple method of locating the depth of foreign bodies with rapidity and accuracy. The tube is moved from side to side and the differences between the rates of movement of the visceral shadows and that of the foreign substance are noted. These depend upon the differences of distance from the tube. If now a probe is placed behind the screen at such a distance that its movements approximate those of the foreign substance, we have the first index of the position of the latter. Repeating the process from various directions, the exact location of it is determined rapidly and easily.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 7, 1901.

The President, Robert F. Weir, M.D., in the Chair.

(Concluded from page 363)

Results of Conservatism.—In Dr. Dudley's 182 cases, 129 resulted in the cure of all symptoms. In most of the cases multiple operations were necessary because the pathological conditions were complex. In sixty cases plastic work had to be done on both tubes and ovaries. In 120 cases the tapping and splitting of cysts was indicated. Out of 182 cases 27 have become pregnant and 22 children have been born at term. In one case, that of a woman forty-two years of age, who had been nine years married, one ovary and tube was removed and the other tube freed from adhesions. A six-pound-boy was born two years later. In this case the woman's condition was so poor that a general anesthetic was not given and the operation was done without anesthesia. In two cases a club-shaped tube was removed and the tube was carefully left open as far as possible. In both pregnancy resulted and living children were born.

Implantation of the Ovary.—Dr. Dudley transfers the ovary in certain cases from its original position to an incision in the fundus of the uterus. This he calls ovarian implantation in contra-distinction to transplantation of the ovary, which consists in removing it from one part of the broad ligament to the other. Dr. Dudley's method when the tubes are destroyed by a purulent degenerative process, or have to be removed because they contain intensely virulent infectious matter, consists in incising the uterus at the fundus and implanting the ovary. In six women in whom this has been done, menstruation has continued and the women have been very well satisfied with the results of the operation. Others have claimed to have done this operation before him, but Dr. Dudley considers that his right to priority in the matter is incontestable. During a recent visit to the continent he was assured by several prominent operators that they were using his method of implanting the ovaries with great satisfaction.

Gynecological Reaction.—Dr. Coe said that sixteen years ago it was not unusual to see tubes and ovaries showing no signs of disease presented at a meeting of a surgical society. Theoretically, conservative gynecology is eminently indicated. In practice, however, its results are not so favorable as to symptoms, anatomy, or pregnancy as some of its protagonists declare. It is very difficult to understand how conservative surgery can be properly done through the vagina. It is impossible to see anatomical details as satisfactorily as is necessary to do hopeful conservative work. The adnexa may be resected, but they cannot well be put back in place. It is not sufficient merely to drop them back into the pelvis, for they are then sure to occupy a displaced position, their blood-supply will be interfered with, and symptoms produced. There was a time when the appearance of a cyst in an ovary was considered good grounds for its removal. Ovaries were removed on suspicion. It is very much easier to do too much than too little. As a rule, patients are not so anxious for pregnancy as for the relief of symptoms. Unless symptoms exist that make life almost a burden, very few women are satisfied to have an abdominal operation done. The necessity for a secondary operation, or even its possibility, will usually lead the patient to decide against conservative gynecology if the case is properly presented. Even with the most favorable statistics only about a six per cent. of sterile patients are made fertile. This is certainly not an encouraging percentage for a serious operation with always the risk of some mortality.

Operative Indications.—Dr. H. J. Boldt said that there are two disease types of special interest: First, those in which there is absolute indication for radical surgery and, secondly, those in which the measure of conservatism is left to the operator. When cysts occur in the ovary, for instance,

they usually occur on both sides. Here there seems a special indication for conservatism. The operation is usually done for symptoms, however, and the puncture of cysts will often not relieve the symptoms. There may be some measure of relief for a time after the operation and then a recurrence of symptoms. It is even questionable whether such cysts have as much to do with the production of symptoms as is often thought. Simple puncture does not destroy them. The cautery seems indicated and yet undoubtedly produces more injury than is necessary. According to the view at present accepted conception takes place in the tube. If the tube is resected, where will conception take place and is there any hope for pregnancy after resection of the tube?

Failure of Conservatism.—Dr. Egbert H. Grandin said that in all the cases of conservative gynecology which he has been able to follow up either a secondary operation had to be done or there was failure to relieve symptoms. This, of course, does not refer to cysts alone, but to gross lesions. The conditions described by the special adherents of conservatism are ideal. Resections of the tube, for instance, cannot be done in the theoretic way described. The conditions being dealt with are eminently infectious. In private practice patients on whom conservative work is done without success fail to return, and so are counted as successful. Other practitioners know better. Where small portions of ovarian tissue are left, the menstruation that occurs is not regular, but very irregular, apt to be painful and too plentiful. The risk of a secondary operation is not justified by the results so far obtained by conservative gynecology.

True Conservatism.—Dr. Philander A. Harris, of Paterson, N. J., said that the operator who tries to preserve enough ovarian tissue to secure pregnancy does not always relieve symptoms as well as he who does a radical operation at once. The woman must be consulted and the case put plainly before her. Amputation and exsection of the tube and resection of the ovary can be done. Conservatism often gives excellent results. Dr. Harris presented a series of photographs from specimens showing what had been accomplished in his practice and demonstrating the success of conservative surgery.

Maternity or Divorce.—Dr. H. N. Vineberg said that conservative surgery in gynecological cases has, in his hands, given some excellent results. In his dispensary practice he comes in contact with a series of sad cases, in which the women come for treatment, not for symptoms, but because they are sterile. If they cannot become pregnant their husbands will get a divorce from them. It is in these cases that the surgeon's skill must be exercised to save every possible bit of tissue and give the woman some chance, however remote, of becoming a mother. Some of the bad results that are complained of are really due to the fact that there are, in addition to disease of the adnexa, pathological conditions of the uterus. These should be treated, either at the same time as the adnexal disease, or later. Before there is any question of absolute failure, all uterine conditions must be relieved and modified as far as possible.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Stated Meeting, Held November 14, 1900.

The President, W. L. Baner, M.D., in the Chair.

Rhinoscleroma, With Presentation of Patient.—Dr. H. Jarecky read a paper on this subject with report of the case presented. (See MEDICAL NEWS, p. 420.)

Discussion.—Dr. Beaman Douglass said the case was particularly interesting from various standpoints. The sessile tumor which appeared first in the case was probably not present when the patient went to the different dispensaries. If the patient had that growth, it would have been amputated. In this case the diagnosis rested between tuberculosis, syphilis, new formation, lupus and rhinoscleroma. The day has passed for thinking only those cases rhinoscleroma in which there was a change in the external nose. Probably this was such a case in the start, because it was difficult to explain the absolute shutting off of the pharynx from the nasal cavity without the involvement of the posterior tips of the turbinated bones. This disease certainly was not produced by a malignant growth; new growths were generally unilateral, and this was very extensive and bilateral. As to its being a case of atrophic tuberculosis, it was certainly an atrophic process, but the characteristic active inflammatory condition and induration which tuberculosis always shows had been absent in this case, together with the absence of lung involvement, and the impossibility of any case of tuberculosis with such an extensive involvement of the throat living to tell the tale; therefore, tuberculosis was excluded. Syphilis was likewise excluded, not only from the history of six perfectly healthy children, and the absence of any miscarriage, the absence of skin infection, absence of lymph involvement, but also because there was no destruction of the deeper tissues. A case of syphilis which would have produced so extensive an atrophy or so extensive cicatrization, would also be accompanied by a destruction of the arytenoid cartilages, the thyroid cartilages and the nose, and possibly of the deeper structures of the septum. Lupus was also entirely excluded, not only from the absence of ulceration, but also from the absence of the characteristic cicatrization.

As to the nature of the tissue which had been formed in this case, it was a peculiar lesion. It was something which American pathologists have not had much opportunity to examine, but was described fully by foreign observers, who see a number of these cases in

Russia and the Eastern part of Austria, as a granulation growth. It is produced undoubtedly by a coccus or bacillus identical with the pneumonia bacillus. It is a slow chronic granulation formation. In the subepithelial parts the bacillus develops slowly, and as it does so, instead of breaking down the tissue by the formation of new cells, as syphilis does, or as the bacillus of lupus does, it formed an infiltration of large polypoid cells in the connective tissue, resembling the early cells of tuberculosis. These cells undergo a degeneration and are known as Mickulicz cells. The bacillus remains for a long time in the tissue. It begins in the nose, and gradually extends throughout the respiratory tract, invading finally the pharynx, and, sometimes even the smaller bronchi. The speaker had seen cases in Vienna where Prof. Schrötter by his ingenious instrument, the bronchoscope, was able to demonstrate the rhinoscleroma nodule in the bronchus on the right side of the lung, and the clinical exhibition of the obstruction of the lung was verified by examination.

The prognosis of the disease is perhaps not as hopeless as held by foreign observers. One point of great interest in this case was that it seemed to be getting well in this climate, under more favorable conditions of hygiene.

Treatment.—On the other side, the tendency had been to operate and the results from the operation have not been good. Prof. Chiara had abandoned all operations except curettage. He tried splitting the larynx so as to reach the growth from the external wound, but has been disappointed. The disease is apt to reappear. Medicinal applications were of no use, the more favorable treatment being to keep the parts clean, put the patient in a healthy hygienic condition, attend to baths, give the patient a highly nutritive diet.

In the pathological cure the patients get well by a cessation of germ activity, and the bodies of which it was composed gradually disappearing. The hyaline bodies last for a long time, but they sink into the deepest structures of the tissue, leaving the surface, and lie at last near the muscular layer. They disappear and after years connective tissue takes the place of the growth, causing a cure of the disease by cessation of the rhinoscleromatous process.

Dr. Francis J. Quinlan said that conditions similar to the one under discussion were often seen, where in early childhood there were marked destructive lesions, following diphtheritic ulcerations. Scar-tissue was peculiarly susceptible in some to different forms of inflammation, although the present patient presented no evidence of this. He thought syphilis and laryngoscleroma were the only points at issue. There were evidences of subacute inflammatory points that closely resembled syphilitic ulceration, without having any marked destruction of tissue, still, syphilis gave just such conditions in the throat and why not in the oropharynx. Very frequently these forms of latent syphilis will not readily respond to antispecific measures. There may be conditions going on in the deeper structures, especially those of the larynx, where extensive and severe lesions are apt to advance on without responding to remedial agents.

Dr. Wolff Freudenthal said that there is no doubt that hygienic as well as climatic and telluric conditions have an influence on the duration of the disease; but naturally there must be other factors about which little is known. He agreed with the previous speaker that there could only be a question regarding diagnosis between syphilis and the diseases comprised under the name of scleroma. It certainly is not a case of tuberculosis. Dr. Jarecky alluded to a paper written by Dr. Freudenthal seven or eight years ago, on so-called Stoerck's blennorrhea. At that time Dr. Freudenthal said that Stoerck's blennorrhea, laryngitis sicca and rhinoscleroma should be grouped together. He has shown two cases of laryngitis sicca, which had developed into typical cases of Stoerck's blennorrhea. The glottis was wide open in the beginning, and came down to a small half-moon-shaped gap, and all the other symptoms of Stoerck's blennorrhea were present. The speaker hardly thought "the case was practically cured." The disease commenced in the pharynx and trachea and the patient will, surely at some future time, have more trouble from the disease. One may be forced to perform tracheotomy, as has been done in many other cases. Dr. Freudenthal showed a picture of the case he reported six years ago. The patient is no longer his friend, because he would not testify in Court that said patient's physical troubles came from a railroad accident. This man wore a tracheotomy tube for about ten years, and his condition had not changed much for the worse, although he lived in the filthiest and dirtiest neighborhood. In regard to the statement made by a previous speaker, that perhaps more cases get cured here on account of cleanliness, etc., the speaker could not understand in what respect cleanliness can cure scleroma of the trachea or of the larynx, although he admitted that the disease originated in a dirty nighborhood.

Dr. George T. Jackson said that, as a dermatologist, he was interested in the disease as it began on the skin and anterior part of the nose. He asked Dr. Douglass how many of the fifty cases of which he spoke appeared on the skin of the nose. He had seen three cases of rhinoscleroma affecting the nose and nasal septum. One case he saw within a year. It was Dr. Freudenthal's case. He turned up in the Dermatological Society, under somebody else's guidance. Another case was a case of his own, of which he showed a picture.

He had seen another case, which had developed in this country, a boy, who lived in the neighborhood of Buffalo, and never had been outside of the country. Dr. Wende of Buffalo, brought him to the New York Dermatological Society for confirmation of his diagnosis. This case went on more rapidly than most cases and the boy died. He responded to all the tests in the way of bacteriology, etc.

Diagnosis by Microscopical Examination.—Dr. Douglass said he did not remember exactly, except that he saw very large noses on many of these rhinoscleroma cases. It was not common to have the external part involved, as well as the internal. The time was past when diagnosis was made only when the external nose was involved. The diagnosis was made from the appearance of the lesion. In Vienna, if the case comes from Russia, they take out a piece of the tissue and find the characteristic condition, the presence of the pneumobacillus and the hyaline degenerated bodies. When these came from the nose and throat, it was called rhinoscleroma. However, it was quite frequent to find in these Vienna cases, and some in Hamburg and Berlin as well, that they were frequently associated with advanced destruction of the skin and enlargement of the nose. The diagnosis could not be made from syphilis except under the microscope. Most of them were in a much worse condition than the case just presented, because the pharynx and larynx were covered with nasal pus.

Dr. Jarecky, in closing, said if this condition was caused by diphtheria, there would be adhesions, but no cicatricial bands. The bands extend posteriorly from the pillars across to the lateral walls of the pharynx. He particularly inquired of the patient as to whether she had suffered from diphtheria. As regards syphilis, he put this patient on antisyphilitic treatment and it only made her worse. There were absolutely no lymphglands enlarged. Baurowitz, in one hundred cases of scleroma, mentioned particularly the loss of the uvula as a distinct diagnostic point; and although it would be lost in syphilis, there would be a loss of substance, but there would not be a smooth, cicatricial scar, as this patient showed. As regards Dr. Freudenthal's statement, that the process began in the trachea, he hardly though that was true in this case. The patient had complained of dyspnea and troublesome breathing for the last ten months, whereas she had sought treatment four years ago, for a trouble in her throat, and had a mouth-wash prescribed. It must have begun in the throat and was still active in the lower parts. As regards tracheotomy, he thought that would not be necessary, as she had received relief from the intubation tubes. No. 1 had been passed two or three times; and as they dilated and ran up the scale, she would obtain more relief. With regard to Dr. Jackson's question, as to in how many cases the external nose was affected in the Vienna clinic, as reported in an article published in the June number (1900) of the *Archives of Rhinology and Laryngology*, the author, in speaking of one hundred cases, mentioned one in which the nose alone was affected.

Vertigo.—Dr. Martin A. H. **Thel**berg read this paper. (This will appear in a future issue of the MEDICAL NEWS.)

Discussion.—Dr. Max Einhorn said that the speaker did wisely in limiting his remarks to those cases of vertigo which emanate from some disorders of the digestive tract, because, otherwise, the subject would be too lengthy for the evening. There was no doubt that there existed a vertigo that was to be ascribed to disorders of the digestive tract, not only to hypersecretion, hyperacidity, but also to disturbances with decreased secretion, or *with* an entire absence of secretion in the stomach.

Not Auto-intoxication.—A great majority of physicians have been inclined to assume some kind of auto-intoxication from the stomach and intestines. Some time ago, in another Society, in a discussion on auto-intoxication as producing the nervous symptoms in constipation, the speaker did not favor this view. The reason for this was that he often saw cases in which there was too much acidity, and vertigo was caused by that acidity, disappearing in five minutes by giving an alkali. This could not be done if the vertigo had been caused by some process of auto-intoxication.

Treatment.—With regard to the treatment of the stomach and digestive tract, these cases will have to be handled individually. There are so many things that may cause vertigo that each should not be treated in the same way. Some patients had intestinal catarrh, which was often the cause. They should be thoroughly examined and the abnormal condition found and treated. Thus in habitual constipation, regular movement of the bowels should be accomplished. If there is catarrh in the intestines, this should be treated. We must always first know the exact condition, before trying to remedy the disease. Often in these cases there were distinct gastric symptoms; nausea, some vomiting, and sometimes the stomach was not to blame for these troubles. One could not be guided by symptoms alone, and should examine all the organs as far as possible. The eyes and ears should be examined. There are always a certain proportion of cases that could not be remedied. He spoke of one patient, who was troubled for a year and a half. His vertigo was connected with fright and it was so pronounced that he was afraid to go to church, or to go to any social entertainment. He would get palpitation, could not do anything, and it disturbed him a great deal. The speaker found some hyperacidity of the stomach and corrected that. He felt his gastric symptoms

were better, but the original trouble was not entirely remedied, after a treatment of four or five months. In the majority of cases of vertigo the treatment is successful. Every day he saw patients who complained of dizziness and vertigo, caused by the stomach or a disorder of the digestive tract, and they quickly recovered. He thought the subject was of great importance, and the Society should be thankful to Dr. Thelberg for bringing it to their attention.

Vertigo a Symptom.—Dr. E. D. Fisher thought that vertigo should be regarded as a symptom. It was only a symptom of a disease in the class of cases which the writer of the paper had given, and was the result of the various disturbances of the intestinal tract and the stomach. Wherever vertigo was a constant symptom, something that was with the patient at all times, one must look for something different than stomach and intestinal troubles. For the direct cause of that dizziness or vertigo, the brain should be thought of as the seat of the disturbance. It might be a dilated stomach, a condition of toxemia or some other cause which affected the action of the heart, and naturally affected the circulation of the brain. When a local condition, such as an intestinal disturbance, was relieved the vertigo was helped. There is a large class of vertigos which are not at all due to intestinal or stomach trouble, although they might be largely influenced by such. There are patients who have diseased arteries, in whom disturbances of the intestinal tract can produce vertigo.

Dr. L. Marcus did not agree with the writer of the paper that the general practitioner failed to recognize these symptoms. In looking over the literature, he found that most of the works on the stomach, intestines or general medicine acknowledge its existence, but it appeared to him that it was the neurologist who disputed its existence, and it is on this account that he feels certain that the general practitioner recognizes, and treats it successfully, so that few cases come into the hands of the neurologists, thereby causing the general doubt among them of its existence.

Dr. R. C. Newton said there were a number of causes of vertigo that had not been mentioned. It would take too long to go into them all. In general practice one frequently meets with vertigo, more or less pronounced, which may be due to malaria, overeating, nicotine poisoning, working too long in the impure air of class-rooms, and want of muscular exercise; although undoubtedly the vast majority of cases of true vertigo are due to one, often two principal causes mentioned here this evening, namely, either gastro-intestinal disturbance or arterior fibrosis.

Dr. George McAuliffe said that, apart from the local causes of vertigo, such as cerebral causes, a constant factor in all vertiginous attacks was the change in circulation, whether that be induced by stomach or intestinal disorder, or by any other organic trouble. It was a curious fact, however, that the semicircular canals, despite the arguments brought to bear that the organ of equilibrium does not reside there, were directly responsible for attacks of vertigo. He spoke of a case of his, where a slight pressure of the probe produced vertigo, a clear demonstration of the intimate connection of the semicircular canals with the equilibrium. He referred to a case of sclerosis of the middle ear, in which the patient was troubled with attacks of vertigo, which came on at times when they were least expected. He would be walking along the street, and immediately would reel to one side and be compelled to grasp some post to prevent him from falling. The attacks lasted for a few minutes. He found by observation that a good dose of bicarbonate of soda would clear the condition in five minutes. It improved his hearing; as he expressed it, opened his head, independent of any condition of the stomach at the time. There were many cases of heterophoria that caused vertigo. One patient of his at present could not go down the stairway in the theatre or house without getting vertigo. She had to close her eyes and feel her way, one stair at a time. He thought one of the chief causes of vertigo, and the only constant factor in the cases of vertigo outside of the direct cerebral effects, was the circulatory change which was established reflexly.

Dr. Joseph F. Terriberry said that his experience was somewhat at variance with that expressed by Dr. Fisher, namely, that persistent vertigo indicated cerebral trouble of an organic nature, due to arteriosclerosis, and is, generally speaking, in accord with that of the author of the paper. In this connection, he mentioned a case now under his observation. A man past middle life, generally healthy, of good ancestry, with normal muscular system, has for from twelve to fifteen years been greatly troubled by poor gastro-intestinal work, the result apparently of faulty hygienic and dilatory habits. During this while, he has suffered from constipation, absence of appetite, lack of energy, very restless nights due to disquieting dreams, and twitching of his muscles, so violent at times, as to awake him from sound sleep, and more or less frontal headache and dizziness at longer or shorter intervals, during this time. Eight months ago he had an epileptic fit at five o'clock in the morning, and these attacks have recurred at intervals of from three to six weeks since then, and always at the same time. A careful examination failed to discover any organic disease. Correction of his gastro-intestinal condition by hygienic, dietetic and medicinal measures, has resulted in a cessation of the epileptic seizures, disappearance of the vertigo and other head symptoms,

restored appetite and regular bowels. Here, then, is a man who has been troubled with vertigo for from twelve to fifteen years, and who presents no evidence of organic disease.

Dr. Jarecky said he wished to call attention to one peculiar case of vertigo. Dr. Koles had been treating this case for a time and referred it to the speaker, thinking it might be caused by the eyes. He found over the cornea a little ulcer, gave a wash, and, on healing, the vertigo disappeared. The patient had vertigo for ten days while Dr. Koles treated her, and continued for another ten days till the ulcer healed.

Dr. Thelberg, in closing, said that the point which he wished to emphasize was that with the general practitioner gastro-intestinal vertigo was the most common. He had had a case of recurrent vertigo, which really was the cause of studying up the subject. On looking through all the authorities, he found that everybody differed. This patient had been treated for heart-disease by different practitioners for a long time, but she had no heart-lesions. She could not leave her home alone, because, if she crossed the street she had to rush with outstretched arms and catch hold of something. She could not go in the street-cars. The speaker treated the digestive disorder and cured her. He did not deny that disease of the semicircular canals, as well as other etiological factors, may cause vertigo, but the affection in the majority of the cases was due to gastro-intestinal disorders.

BOOK REVIEWS.

Studies of American Fungi; Mushrooms, Edible, Poisonous, etc. By George Francis Atkinson, Professor of Botany in Cornell University. Andrus and Church, Ithaca, N. Y. ($3.00 postpaid).

This book on American mushrooms is a work of high economic value, and is beautifully and profusely illustrated with photographs of the fungi taken in their natural states. While it is a thoroughly scientific study of the higher group of fungi, it is written from a broader standpoint than that of a mere systematic study. It indicates the edible fungi clearly, and points out the poisonous ones that resemble them.

Americans do not avail themselves of the bountiful supply of table-mushrooms that grow in the woods and fields as eagerly as do dwellers in European countries. There even the poor know a large variety of the fungi that make an excellent substitute for meat, but it is hoped that the impetus given to mushroom-collectors by the work of the late William Hamilton Gibson will be continued by this more complete book.

Mushroom-hunting has grown to be a fad among physicians during the last few years, especially in Boston, Philadelphia and New York, where every busy man needs an incentive to get beyond the city-limits; and in a number of laboratories and dens the chafing-dish has its place along with more prosaic apparatus. The contribution by Mrs. Rorer of a chapter of receipts for cooking mushrooms will add a very practical value to the book.

Dr. Atkinson's book, however, is not only for the man who collects mushrooms for amusement. It is an authority on the subject of the toxicology and chemistry of mushrooms; and by means of its photographs and descriptions of the deadly species, the physician can at once verify any poisonous species that has been eaten by mistake.

It supplies the most concise and complete recent resumé of the subject of mushroom-poisoning that has yet been published, and for that alone should be on the shelf of every physician, especially in these days when the sudden interest in mushrooms is leading enthusiasts to try everything they find.

An American Text-Book of Physiology. Edited by Dr. William H. Howell. Second Edition. Revised. In Two Volumes. W. B. Saunders & Company, Philadelphia and London.

We have had occasion to praise this excellent work and in its new edition and new dress it deserves even higher commendation. The plan of issuing two volumes instead of one is specially valuable, as the old single volume was one that required athletic arms to handle. In its present form it is handy and comfortable as a text-book and reference work.

The present edition shows some slight changes in the subject-matter; all of which commend themselves as being more in accord with later-day physiology. The chapter on the central nervous system has been altered more than any other and, it should be said, greatly to the advantage of the work. The previous mode of presentation left much to be answered and was quite inadequate for the purposes of the student. The present chapter, however, is certainly most commendable and, when read in conjunction with the chapters on the special senses, affords a most comprehensive view of the present knowledge of the functions of nerve-structures. Taken all in all, this work reflects the high quality of American physiological activity and is deserving of a generous appreciation.

Studies from the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York. Vol. VII. For the Collegiate Year, 1899-1900.

The present volume, made up of reprints of articles appearing in current medical literature, is highly suggestive of the excellent quality of the work done in this well-equipped laboratory. In all there are some fourteen studies covering a wide range of pathological inquiry.

VOL. LXXVIII. NEW YORK, SATURDAY, MARCH 23, 1901. NO. 12.

SPECIAL ARTICLE.

RETROSPECTS AND PROSPECTS IN GENITO-URINARY SURGERY.[1]

BY REGINALD HARRISON, F.R.C.S., ENGLAND,

OF LONDON;

LATE HUNTERIAN PROFESSOR OF PATHOLOGY AND SURGERY OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ALTHOUGH I have but two or three days in your great city, my friends, Professor Dennis and Professor Alexander, have afforded me the privilege of addressing you. I must disclaim at once any intention of giving you anything that is either original or novel. I shall talk of retrospects and prospects in genito-urinary surgery. The end of an old century, the beginning of a new one very naturally makes us look before and behind us. We pick out the landmarks of the past and are tempted to peer into the future. To you, just entering on the practice of medicine, the review of some of the achievements of the past may seem like ancient history. The discoveries of times that are no more may well furnish texts, however, for the illumination of the future.

It would be false modesty in me if, in reviewing genito-urinary surgery, I should attempt to pass unmentioned my own contributions to the science as it has grown in the last half century. You will pardon me, then, if I sometimes seem too personal in recalling the advances that have been made.

Litholapaxy.

The most prominent feature in the progress of genito-urinary surgery during the last century was undoubtedly the development by Bigelow of a method of crushing calculi within the bladder and then the added invention which enabled him to wash out the débris of the crushed stone at a single sitting. It was my privilege to see Professor Bigelow at some of his earliest work on this subject and to hear his anticipation of what might be expected from this invention when it was perfected. May I add that all of these anticipations have been realized. Litholapaxy has taken a deserved place as one of the great surgical measures that saves mankind suffering and reduces mortality.

I had the privilege of demonstrating in England Professor Bigelow's method with instruments furnished me by himself. I have seen his method for treatment of vesical calculus replace all others. I had occasion the other day shortly before my voyage to America to look over the old apparatus which he sent me from America. It is, in all essential features, the apparatus in use all over the world at the present moment for the accomplishment of litholapaxy. The invention came from your great compatriot's brain in all its perfection and needed no after improvement to make it completely successful. Very seldom is it the lot of an individual thus to perfect his work before giving it to the world. It is a sure sign of the genius of the man.

Otis' Urethrometry.

Bigelow's work in litholapaxy was undoubtedly influenced by the patient investigations of another distinguished American genito-urinary surgeon. When I had the pleasure of meeting him, in 1878, Professor Bigelow mentioned to me Dr. Otis' investigation as to the size of the urethra and the amount of distention of the healthy urethra would permit without suffering injury. This very practical work of Otis's was almost a necessary preliminary to Bigelow's success. When I saw Bigelow's perfected instrument afterward, I remembered his mention of Otis's work and realized how much he owed to the distinguished New Yorker.

Etiology of Vesical Calculus.

Bigelow's invention has tended also to throw light on the etiology of vesical calculus. Especially the etiological influence of enlarged prostate in the formation of stone became evident as the result of his methods of treating calculus. This influence of the prostate in the production of calculus has been a favorite subject of study on my own part.

It is not generally known that one of the most important contributions to the etiology of stone in the bladder were made as long ago as 1851 by Rainey. His paper was concerned with the investigation of molecular coalescence. He showed that stones could be artificially produced when the solution of certain salts dissolved in urine was disturbed by the presence of unfavorable factors. This chemical side of the origin of stone in the bladder has never been given the attentive investigation it deserves.

It has been a great pleasure to me to be conducted through this magnificent building by my friends among the faculty. I have seen laboratories and class-rooms and anatomical rooms fitted out in a style that is worthy of this great city and of the new century that is beginning. I have especially admired the magnificent equipment of your laboratory. I

[1] Abstract of an address delivered at the Cornell Medical College, New York City.

can not think of any subject that I could suggest that would be more suitable for your investigation in these laboratories and that would tempt more to research than the etiology of vesical calculus. No subject is more fascinating or more important and the mere repetition of Rainey's experiments would undoubtedly throw light on this interesting subject. It seems too bad that this patient investigation with its suggestive results should so far have proved profitless. Let us hope that the new century and American enterprise will make that use of them they deserve.

Prostatic Hypertrophy.

In 1893, Professor J. William White of Philadelphia announced a new method for the treatment of prostatic hypertrophy. On theoretic grounds he suspected a close relationship between the testicle and the prostate. He demonstrated experimentally on dogs that the removal of the testicle led to a decrease in size even of the normal prostate. He argued that the excision of testicles in the human being would probably lead to a reduction in the size of enlarged prostate. The method was tried on several patients and the surmise of Dr. White proved to be not without some foundation. Other investigators found that the excision of a portion of the vas deferens had the same effect on the prostate as the excision of the testicle.

This method of treating prostatic hypertrophy has given rise to a good deal of controversy. Undoubtedly the method of treatment, whether by removal of the testicles or vasectomy, has given a certain measure of successful results. Those results are so variable, however, as to leave the subject almost more obscure than before. In certain cases the measure of relief afforded is very striking. In others practically no good is accomplished. The whole subject requires reinvestigation and will well repay any work that may be done on it.

Meantime these seven or eight years during which Professor's White's work has been the subject of controversy have not been wasted. We are beginning to recognize now better than ever that under the term, enlarged prostate, or hypertrophy of the prostate, there are included not one but many pathological conditions. To talk of enlargement of the prostate simply without any further definition of the term is now almost as crude and unscientific as if a surgeon were to talk of enlargement of the breast without defining the different forms, of enlargement of the tonsils without explanatory differentiation. Our success in the treatment of prostatic hypertrophy depends on our ability to differentiate the various forms of the disease which occur. We need to determine precisely the character of the enlargement, and for this the only sure means is ocular inspection. A case that illustrates this very well was under my care within a month before I sailed from England. The patient suffered less than two years ago from a stone in the bladder which was removed by litholapaxy. Another calculus formed before the year was out and a second recurrence of the stone took place before the expiration of two years. With a cystoscope I found that there existed a pouch in the enlarged prostate. A tongue of prostatic tissue extended backward into the bladder forming a sort of lid for a box within the folds of the prostate and it was in this that the stones had formed. Besides the stone which had escaped into the bladder and which had been detected by the sound, two smaller ones were in process of formation within the prostatic pouch. I made a median incision and twisted off the tongue of prostatic tissue and the man made a good recovery. Two weeks after the operation he was practically well.

Recently I have described three forms of prostatic hypertrophy. These three are so characteristically distinct from each other that it is very unlikely that they will admit of uniformity of treatment, or that any one method of dealing with them will bring the relief of symptoms in all cases. Since landing in New York I have seen Dr. Alexander's specimens and these have modified my opinion as to the forms of prostatic hypertrophy which exist. Dr. Alexander's specimens certainly extend our information as to prostatic condition beyond what it was before. I am free to confess that they were for me a suggestive chapter in the pathology of the prostate. I have not been wedded to my own divisions in prostatic pathology and the modification of my views since seeing the specimens here forms a good illustration of the fact that we must not be ready to formulate cast iron distinctions that will admit of no modification. I must take this occasion to express how much genito-urinary surgeons owe to Dr. Alexander and how much we expect from his future work.

The first form of prostatic hypertrophy and one that is of a great deal of interest is the simple enlarged prostrate which bulges upward and backward into the bladder. This form of prostatic hypertrophy is more generally cured than any other by castration, vasectomy, or by the Bottini operation. What Bottini's operation really accomplishes in these cases is an obliteration of the upper projecting portion of the enlarged prostate which because of its projection in the trigone is interfering with urination.

The second variety of prostate is the one that I have already described in speaking of the relapse of stones in the bladder. In these a tongue of prostatic tissue or a median lobe of the prostate is the active agent that interferes with the emptying of the bladder. For these cases castration or vasectomy as a rule does absolutely no good. The median tongue of tissue must be removed.

The third variety of prostatic hypertrophy is that in which there occur in the midst of the enlarged prostate hard glandular growths, adenomata they really are. For this form of prostatic hypertrophy castration and vasectomy are always failures and Bottini's operation will invariably be done without success. I shall never forget one of my first experiences with this form of enlargement of the prostate. The case was one in which for the removal of a large stone in the bladder, a suprapubic lithotomy was done. The stone was removed without any difficulty and, in passing my fingers around the base of the bladder in order to be sure that no small calculi were left, I shelled out one of these adenomata. It came away without any bleeding and required very little effort for its removal. No other method of treatment would have been successful, however, in relieving the symptoms of enlarged prostates or in preventing recurrence of the stone.

What is needed at the present moment then is not further discussion of the merits of castration and vasectomy, nor of the limits of utility of Bottini's operation, but a precise diagnosis of the form of prostatic hypertrophy which really exists in individual cases. In prostatic surgery as in every other branch of surgery that has developed during the past century, what is needed is more accurate diagnosis with adaptation of the treatment to the specific affection which exists and not the application of general methods to a supposedly general condition which has no existence in individual cases.

Surgery of Kidney.

The surgery of the kidney even in its present stage may be regarded as one of the most important advances of the century that is just passed. What has been done for renal stone, growths, distentions with pus and urine, abnormal mobility and other painful affections of this part is sufficient to indicate this. Nor is it at all likely that we have reached limits in the surgery of the kidney which cannot be extended much further with great advantage. The interesting question for us just now, however, is, What is there in the future of the surgery of the kidney? Is there, for instance, anything that can be done by surgical means for the relief of albuminuria, or for the prevention of the development of degenerative conditions. There is no doubt that albumin has been found for long periods in the urine in connection with stone or abscess of the kidney and that after the surgical treatment of these conditions the albumin has disappeared and the patient has completely recovered.

A very interesting subject that I discussed in a paper that appeared some years ago in the *Lancet* seems worthy of consideration here. I allude to the effects of tension arising out of excessive excretory efforts on the part of the kidneys and resulting in congestion and inflammation which in some instances are probably more disastrous and far reaching in their local consequences than the severe surgical conditions of the kidney already mentioned.

There is no more delicate organ in the body than the kidney. There is no doubt that the delicate, complicated, secretory structure suffers severely from congestion. When the congestion is intense, lasting harm may be done. In several cases I have had the opportunity to see congested kidneys in the very acme of their congested state. They are not only of a deep color that is almost black, but the capsule of the kidney is tense and shining, because so overstretched. If such a kidney is punctured during an exploratory operation upon the kidneys the blood is found to be present in it under great pressure, so that it gushes forth.

There is no doubt that this pressure, as in the testicle, may work serious and lasting harm. It is not improbable that under circumstances like these, lesions are produced which lead to the formation of connective tissue and prove the foundation of the hypertrophic and atrophic condition of subsequent chronic nephritis. Renal glaucoma is the name that to me seems most suggestive for this condition.

I had occasion to say some years ago that if certain organs of the body occupied other positions than those where Nature has placed them a variety of morbid conditions to which they are respectively liable would receive somewhat different treatment from that which has hitherto been adopted. Of the complex organs of the body the eye furnishes us with the best example of what surgery is able to accomplish in removing obstacles and impediments to vision and in combatting the disastrous effects of intraocular tension and the degenerations arising therefrom.

Modern antiseptic surgery, however, has brought even the internal organs of the body within the range of the surgeon's skill without imposing any very great risk on the patient. For the condition of congestive tension in the kidney, an aseptic exploration with puncture of the capsule might easily be done without great danger. This operation would perhaps serve as a prophylactic against the development of kidney disease later in life. I have had some personal experience with cases of this kind that have proved very encouraging. Others have taken up the subject in a way to make me think that this idea may be developed successfully. At the next session of the British Medical Association there are two questions that I have proposed to set down for discussion.

First.—To what extent may kidney tension, as in inflammatory conditions and congested states, be responsible for the serious damage in these organs that often follows. Is this excessive tension the etiological factor in chronic degeneration, or chronic Bright's disease? In a word does the expression renal glaucoma

convey an idea that is important in kidney pathology?

Second.—When is it expedient and justifiable to relieve this tension by exploratory laparotomy and puncture of the capsule of the kidney?

The kidney and its functions remain as yet a great mystery. The urine is an extremely complicated solution and its suppression may cause the most serious symptoms. Re-absorption of its constituents may readily give rise, as every genito-urinary surgeon knows, to septic conditions. The irritation of a simple bougie, or of a sound, or the wound produced by urethrotomy may easily prove the point of serious infection when urine is passing over it. Long ago under Lord Lister's influence I suggested the use of boracic acid as a prophylactic for these septic accidents. It has proved of great service to the genito-urinary surgeon, but there still remains a large field for investigation as to the ways and methods of making the urine aseptic.

The understanding of urinary tuberculosis is a chapter and a very important one that is just opening up. Janet and Guyon and Albarran have been doing good work in this specialty and the obscurities of pathology and of clinical observation are clearing up.

At the present time good men are at work all over the world in the specialty of genito-urinary surgery. It is no wonder that we have advanced. Practice of the specialty has become a most honorable profession. Great advances can be looked for in the new century that is opening up and especially in this new country where you have the enterprise, the equipment, and the opportunity for the work.

ORIGINAL ARTICLES.

CEREBROSPINAL MENINGITIS (WEICHSELBAUM, JAEGER) TREATED BY REPEATED LUMBAR PUNCTURE.

BY HENRY KOPLIK, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN IN CHARGE OF THE CHILDREN'S WARD, MT. SINAI HOSPITAL, NEW YORK.

Cerebrospinal meningitis, whether epidemic or sporadic, is now recognized as an acute infectious disease the direct inciting cause of which is a micro-organism. The bacteriological investigations open to us on this very important subject divide themselves into two distinct groups. A large number of cases investigated by one group of observers corresponds to a type of disease which thus far seems to have occurred either in small isolated groups of cases, or in localized epidemics in barracks or military hospitals. These cases have been met also in large and more disseminated epidemic groups.

In this type of disease we find bacteriologically one distinct and constant micro-organism. This is a diplococcus which has been found either in the fluid withdrawn from the arachnoid by lumbar puncture during life, or in the exudate on and about the meninges post-mortem. It is seen mostly in the pus cells, sometimes outside of the same. It has a form very similar to the gonococcus, is decolorized by Gram and reminded the earlier observers of the gonococcus. This is the so-called *diplococcus meningitidis* of Leichtenstern, Weichselbaum, Jaeger, Heubner, Finkelstein, Councilman, Mallory, Wright, and many others.

These cases have been accepted by Weichselbaum, Jaeger, Councilman and Osler to correspond to the type of so-called epidemic cerebrospinal meningitis of older writers. We cannot conclude, however, that these cases in which the *diplococcus meningitidis* is found represent the only forms of cerebrospinal meningitis. There is another group equally as large, if not larger, in which a number of observers, whose skill and accuracy is undoubted, have found a micro-organism which corresponds to the *diplococcus pneumoniæ* of Fraenkel. These cases also have occurred in epidemics or large groups. It seems, however, that these cases have for the most part been complicated with lobar or bronchopneumonia or have followed as a complication of otitis media.

In order to reconcile the diverse bacterial results in both these groups of cases, Netter, Foa et Burdoni Uffreduzzi, and Baumgarten have attempted to show that the etiology in the cases of cerebrospinal meningitis caused by the *diplococcus meningitidis* and that of the cases caused by the *diplococcus pneumoniæ* was identical. The intracellular diplococcus of Leichtenstern, Weichselbaum and Jaeger was with them only a degenerate form of the diplococcus of Fraenkel.

To accept this theory would be to overthrow the unity of etiology of most diseases, a position no one is willing to assume. We must to-day thus recognize that there are two distinct groups of cases, one of much severer course and of a more fatal character, usually complicating or occurring with lobar pneumonia or bronchopneumonia caused by the *diplococcus pneumoniæ*. The primary affection, however, of cerebrospinal meningitis, if we accept the investigations as they stand in the literature, is caused by the intracellular diplococcus of Leichtenstern, Weichselbaum and Jaeger, the so-called *diplococcus meningitidis*.

To-day, the important question is whether this disease may occur sporadically. If so, then cerebrospinal meningitis is a disease which occurs epidemically and sporadically and in both forms has a similar etiology and symptomatology. One peculiarity of this disease is that cerebrospinal meningitis is scarcely epidemic in the same sense as typhoid fever, scarlet fever or measles, or even diphtheria. We rarely find that several members of a family are attacked. If we study the liter-

ature—and this is well brought out by Councilman—it is seen that the disease occurs epidemically in the sense that a large number of cases will occur at one time or at one season of the year. The cases crop up at distant parts of a town or city widely separated from each other. The disease has no great tendency to spread. It seems to localize itself in groups in the places in which it occurs. This is well illustrated in the epidemics reported in barracks in which the disease has in few instances shown a tendency to spread outside these military stations to the populace of the town or city in which they were situated, and this only to a limited extent.

The epidemic reported by Councilman is one of the largest. In this epidemic a glance through the cases shows them to be isolated ones. The map shows the groups of cases occur widely separated. In this respect the comparison by Osler of this disease to pneumonia may be apt.

Henoch raises the question as to what in this disease can be called the epidemic and what the sporadic occurrence of the disease. We certainly would not call a group of eight or ten cases an epidemic. It may represent a local outbreak of exceedingly limited character. Scarlet fever is very much of this nature; we have local outbreaks of the disease constantly epidemic, but rarely epidemics. If we have the isolated occurrence of a small number of these cases; if such cases come to us from streets widely separated; if such cases also extend over a number of months, we may fairly call them sporadic.

It is to this important group of cases, the sporadic form of the epidemic cerebrospinal meningitis type, as it occurs in children, that I refer. Of the 111 cases studied by Councilman 29 occurred in infants and children below the tenth year of life. It is, therefore, quite frequent in this class of subjects. There are no large epidemics among children on record in which detailed symptomatology is given. If we analyze the epidemic cases of Councilman, we find a striking similarity in the symptomatology. If the case was that of an infant, the disease set in quite regularly with convulsions, soon followed by unconsciousness, rigidity of the muscles of the neck (*genick starre* of the Germans), and opisthotonus. In older children the symptoms of invasion were headache, fever, vomiting, stiffness of the neck, delirium and opisthotonus. The subsequent symptoms found in the summaries of Councilman's cases are much the same. The fever continued, there were chills, delirium, *tache cérébrale,* opisthotonus, herpes, roseola, the pupils in some cases being unequal, in others there was a total or partial blindness. In a few cases otitis is noted. Hyperesthesia and tenderness of the muscles of the neck, diminished reflexes, and finally arthritis make up the points found very briefly noted in the *résumé* of cases.

The vomiting may occur at the outset or in the course of the disease and is cerebral in origin. It may occur during the disease and prevent the taking of food (Councilman). The delirium may be either of a low muttering character or of a violent nature. There may be intervals of consciousness alternating with delirium. Pain in the back of the neck, extending over the whole body and amounting to hyperesthesia, may be present. Headache was intense. Patients were extremely sensitive to touch.

Rigidity of the muscles of the neck in some cases extended to the muscles of the back. It was present in all but 29 of Councilman's patients. As is well known, it is the characteristic symptom of the disease and has led the French to the adaptation of the German term *genick starre* as the most characteristic of the symptoms. Coma varied in intensity from day to day and alternated with periods of stupor and consciousness. Paralyses were infrequent. Facial paralysis was present in two patients. In another patient paralysis of the leg was noted. In another hemiplegia.

The skin lesions, generally petechial, which have led to the name of spotted fever, are not noted to a marked degree in the more modern epidemics. In the children in Councilman's set of cases we find erythema, petechiæ, hemorrhages and herpes. In the fatal cases petechiæ and hemorrhages are noted.

Eyes.—In cases of the childrens' series we find conjunctivitis, desiccating keratitis, strabismus, contraction and dilatation of the pupils with little or no reflex action of the pupils, inequality of the pupils, neuritis of varying grades from reddening of the disc to violent inflammation of the choked disc variety, postneuritic atrophy and purulent choroiditis (Edwin E. Jack, Boston Children's Hospital).

Ear.—Ear symptoms in many cases vary from plain deafness to otitis with discharge from the ears or even mastoiditis. The ear complications which have been especially studied by aurists in children may amount to complete deafness or may affect the gait. The child in such cases walks with a swaying tottering motion (Gahlberg, Councilman).

Nose and Throat.—In most epidemics the secretions from the nose and throat have been examined, and it was found that they contained diplococci which decolorized with Gram. Councilman examined fifteen patients, in ten of whom he found diplococci as above.

Joints.—These were affected in adults (Osler, Councilman). We find no joint complications in the children. The blood showed leucocytosis. The temperature and pulse will be considered later.

If we study the cases either of sporadic or epidemic cerebrospinal meningitis in the older text-books on diseases of children, we see that the writers seem to regard the cases which occur sporadically and those which occur epi-

demically as distinct. The symptomatology of the epidemic cases is much what we find it in the present epidemics. Some writers, such as Henoch, are not quite certain as to whether they should regard the cases occurring in small groups as being similar in etiology and symptomatology as the cases occurring in epidemics of larger numbers. For my part, I would regard cases as sporadic which occur in very small limited groups, the isolated cases having no relation with each other. The absence of anything like an extended epidemic is also an important guide and the occurrence of the cases at long intervals, though in the aggregate they may amount to six or ten cases in a hospital service in the course of the year.

The cases which I report were those occurring in my hospital service in the past year. The first was admitted April 23, 1900; the second, April 29, 1900; the third, May 3, 1900; the fourth, August 21, 1900; and the fifth October 26, 1900. Two occurred together, but had no relation to each other. We may fairly call such cases sporadic. They lived in widely-separated parts of the city, and there could not be traced any relationship between these cases and others of a like character.

The symptoms of invasion in the youngest patient, an infant eight months old, are the most interesting. They began with a conjunctivitis six days before admission, which conjunctivitis preceded meningeal symptoms. The infant developed convulsions and went into a semicomatose condition with a febrile movement, but no vomiting. In this condition it was admitted to the hospital.

The other cases occurred in older children. In one patient, a boy four and a half year of age, the illness was preceded by a fall on the head. (I lay no stress on this as in most children there is an indefinite history of a blow or a fall.) In this case the initial symptoms were vomiting, fever, difficulty in swallowing, no rigidity of the muscles of the neck, and general convulsions followed a day before admission by stupor. In this condition the patient was admitted to the hospital ward.

In another patient, a female child eight years of age, there was a history of being pushed at play and of striking her head against a railing. There was no wound. Five days before admission she complained of headache, vomiting; she became delirious, in which condition, with opisthotonus, she was admitted to the ward. Another patient, a female child nine years of age, complained sixteen days before admission of headache, vomiting, with chills, followed by fever. The chills recurred daily for ten days. The headache was frontal and occipital. The neck became rigid and painful. She became dull and apathetic. In this condition she was admitted.

The last patient was a male child twelve years of age. Three days before admission there was frontal headache with constant vomiting. Fever, delirium, and apathy were also noted. There was also some pain in the stomach.

If we compare the histories of the older children we find the symptoms of invasion much the same. The history of the infant finds its counterpart in some of the cases of Councilman (Case CI.), but it is of especial interest on account of the specific diplococcus conjunctivitis which preceded the meningitis. The other symptoms of these cases after admission may be grouped as follows: Rigidity of the muscles of the neck (*Genick starre*). This was present in all the cases, in some being so pronounced as to give an opisthotonus. There was great pain in the muscles of the neck if any attempt was made to straighten the same.

Cerebral Symptoms.—In most patients there was delirium, stupor or coma; in one simply headache. The headache in cases in which the periods of unconsciousness alternated with delirium or semiconsciousness seemed to be the principal head symptoms. There was great hyperesthesia of the surface in some. The patients would cry out if the bed was jarred or the skin touched. In one infant there were unilateral convulsions.

Reflexes.—The patellar reflex may have been absent; those of the plantar were present. In some patients the reflexes were increased later in the disease. In another patient the knee-jerks were exaggerated on admission. In one case bilateral clonus at the ankle was noted. Babinski's sign was absent in all cases. Kernig's symptom was present in all but one patient and persisted for some time into the convalescence.

Skin Eruptions.—In some there was herpes labialis noted on the upper and lower lip. In others there were successive attacks of erythema, resembling scarlatinous eruptions. *Tache cérébrale* was present in all patients.

Joints.—In one patient there was marked tenderness of the right shoulder, but no swelling. During lucid intervals the patient complained of this pain. In one infant there was felt a peculiar rubbing or friction when the knee-joints were manipulated. There seemed to be slight swelling. In one patient there was abscess of the foot, which when incised revealed pus containing diplococci the exact nature of which remains undetermined.

Eye Symptoms.—These were confined in the infant to conjunctivitis. Diplococci were found in the pus of the discharge, and were obtained in pure culture and decolorized with Gram. The pupils reacted to light. The infant did not seem to see. In the other patients expert examination of the fundus showed ischemia of the arteries of the optic disc. In another, the right eye was normal; the left showed signs of beginning neuritis. In still another the veins of the disc were swollen, and there was some exudation. In this patient signs of neuritis in both eyes persisted until convalescence. There was no palpable impairment of sight. In another patient, there was double

optic neuritis, which disappeared just before the patient's discharge.

Nasal Secretions.—Nasal discharges in the case of the infant showed diplococci which decolorized with Gram.

Temperature.—This was not characteristic in that it might have been seen in any other suppurative process. For the most part the curves showed a daily rise, which at the outset and in the active stage of the disease reached 106.4° F. There is in some patients a distinctly intermittent character to the curve—the temperature reaching the normal daily, or near the normal. In others the temperature was persistently high with remissions daily of a degree or more. The most important parts of the curves are shown here.

Chills.—Repeated chills, violent in character, occurred in one patient in the course of the disease. In the others, reference to the histories show that they occurred at irregular intervals of varying severity.

Circulation.—The pulse showed marked irregularity; the respirations were increased for the most part, varying in the number per minute throughout. This occurred without any disease of the lungs. The heart in one patient showed nothing abnormal on admission, but after the lapse of a month an aortic systolic murmur developed. Another patient had an aortic regurgitant murmur on admission. Inasmuch as in both patients there were no symptoms referable to the heart, we are unable in the absence of an examination prior to the present illness to state positively as to the presence of an acute endocarditis.

Lungs.—The lungs did not give definite signs of pneumonia.

Spleen.—This was enlarged in only one of the five patients.

Paralysis.—Left facial palsy was noted on admission in Case II., and weakness of the left upper and lower extremities. Right facial palsy was noted in the infant, which also had right-sided convulsions toward the close of the disease.

Clinically the cases seemed to divide themselves into three distinct types. In the one class, in which the little patients were not very ill, there was headache, rigidity of the neck fever, and perhaps at night a little delirium; yet the patients sat up in bed with the ice caps on the head and seemed comfortable in the intervals of head pains. They were rational. We had two such patients. One of these is recorded in the histories; the other has been omitted because we did not observe it during a sufficiently long period, the patient's parents insisting on taking the boy home. He had, however, greatly improved when discharged. In another class are the *foudroyant* cases in which death supervened in a short time, as in the infant. The onset of the coma was early; it continued and deepened until the fatal issue. The third type, the usual form, was that in which the patients came in with a noisy delirium. They had rigidity of the neck, stupor, with periods in which they could be roused and made to answer questions.

Lumbar Puncture.—The series of cases which I report were punctured after the method of Quincke at repeated intervals. The effects of this method of procedure and its ultimate results will be discussed in detail under the heading of treatment. In this place the bacterial, macroscopic and microscopic details are of interest. The five cases were punctured fifteen times, including one dry tap. Fluid varying in quantity from 3 to 50 c.c. was withdrawn at each pucture. In the series, punctures were performed on the fifth, sixth, eighth, ninth, tenth, thirteenth, sixteenth, nineteenth, twenty-fourth, twenty-eighth, thirty-sixth and thirty-seventh day of the disease. It will be seen that fluid was obtained at all periods of the process.

If we refer to the table it will be seen that the fluid withdrawn was turbid on the fifth day of the disease; on the sixth day cloudy; eighth day turbid; tenth day turbid and flaky; thirteenth day turbid, thick and purulent; it continued to be turbid up to the thirty-seventh day of the disease. This shows that there may be marked exudate even at an early period, and later puncture after chills may give a turbid, flaky or even purulent looking fluid. Councilman found that a diminution of turbidity went often hand in hand with absence of micro-organisms. In our cases we found micro-organisms in the turbid, opalescent and less turbid fluids. Micro-organisms grew in all the turbid fluids. In the opalescent or clear fluids micro-organisms were found, by stain, and sometimes were absent by culture. They were absent, by culture, in only one of the turbid cases. On the other hand, they were positive in all the cover-glass spreads except one and in this case culture showed the diplococcus. It seems that the difficulty of culture is rather the obstacle to a positive result, in some cases, rather than the abundance of micro-organisms. In all cases there was found a diplococcus which corresponded to that described by Weichselbaum and Jaeger. It answered the test by the Gram method. It was cultivated pure in all the cases and in all the repeated punctures, except in one. The details of the cultivation given to me by the assistant pathologist, Dr. E. Libman, of the Mt. Sinai Hospital, show that in the case in which the culture was negative, the fluid was turbid in both punctures; in both the diplococcus of Weichselbaum was found in the cover-glass spread. In both, culture failed: one culture being contaminated, the other being negative. In the infant, the secretion from the eyes gave pure cultures of the diplococcus of Weichselbaum. The nasal secretion showed diplococci which decolorized with Gram in two cases.

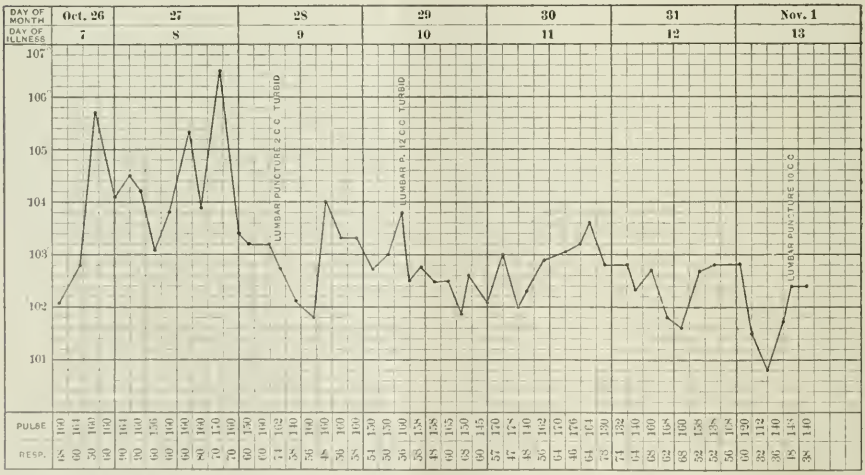
I here append the pathologist's report: "All of the fluids withdrawn, save one, contained

pus cells. The fluids from Case V. also contained mononuclear cells. Secondary fluids contained less cellular elements than the primary ones. None of the fluids contained sugar (one being too small in bulk to allow of an examination). Much albumin was always present. With nitric acid, the rings usually measured from ⅛ to ⅜ of an inch in height. The secondary fluids contained less albumin, except in Case V. Typical diplococci responding negatively to the Gram procedure were found in all the fluids except in Case IV. and the second fluid from Case III. They were usually intracellular and perinuclear, occasionally extracellular. They were usually more abundant in the more turbid fluids. They were present in spreads from the conjunctival discharge and the nasal secretion of Case V.

except in Case VI. Cultures were made from the nose in Case V. only; no diplococci were found in the culture, there being a pure culture of the *staphylococcus albus*. Cultures from the conjunctival discharge showed numerous colonies of the diplococci.

The diplococci obtained in all the fluids were always the same. They all corresponded closely to Weichselbaum's description. They varied much in size in the same colony, a rather characteristic point. They always failed to stain by Gram. Capsules were never present. The growths were very distinct on agar, but better in serum-agar. The growth is very abundant in serum-glucose-agar made by adding one part of serum (preferably human) to three or four parts of 2-per-cent. glucose-agar.

Fig. 1.



Female infant eight months old, unconscious on admission. Chart shows the effect of lumbar puncture on the pulse and respiration. Fatal case.

For cultural purposes, agar, serum-agar, and for Cases III. and VI. a medium made by adding serum to glucose-agar were used—as a rule a few drops of fluid were dropped into each of two or three tubes. These tubes were tilted at frequent intervals so as to allow the condensation water to flow over the medium (Heubner method). Whenever a positive result was obtained a growth was found in all the tubes. The growth was found within twenty-four hours in all the fluids except in that from Case III., which gave a growth only after three days. As a rule the colonies were quite numerous, the more turbid fluids usually giving better growths. All the growths were pure.

The cultures were positive in all the cases

Inoculations made from the best growths on the various agar media in bouillon, or on gelatin or potatoes, were never followed by any growth. Even if glucose and serum were added to the bouillon, inoculations were unsuccessful. The vitality was usually tested by ascertaining for how long a time a growth could be obtained by inoculating from one agar tube to another daily. In Case V. a growth was obtained for eleven days; in Case IV. one day; in Case I. (first fluid) six days. On serum-agar the organisms could be daily transplanted for a longer time. Exact data were not obtained, except that the organism from Case V. after two months is still actively growing on serum-glucose-agar.

Case I.—Lumbar puncture on admission; 2

c.c., turbid; eighth day of disease. Tenth day, 12 c.c., turbid and flaky; fluid did not flow. Thirteenth day, 10 c.c., turbid.

Case II.—Lumbar puncture on admission; nineteenth day of disease; 15 c.c., turbid. Twenty-fourth day, 10 c.c., turbid.

Case III.—Lumbar puncture on fifth day of disease; 40 c.c., cloudy, turbid fluid withdrawn. Sixteenth day, 15 c.c., opalescent, less turbid, Twenty-eighth day, 35 c.c., opalescent fluid.

Case IV.—Lumbar puncture sixth day of disease, 50 c.c., cloudy serum withdrawn. Ninth day, 3 c.c. withdrawn. Nineteenth day. 10 c.c., turbid, higher up. Twenty-fourth day, 30 c.c., turbid fluid. Thirty-sixth day, 16 c.c., turbid fluid.

Case V.—Lumbar puncture on ninth day of disease; 25 c.c., great pressure, turbid. Thirty-seventh day, 5 c.c., slightly turbid. Spread from nose, diplococci decolorized with Gram.

Treatment.—The treatment of cerebrospinal meningitis has hitherto been a palliative one. Recognizing the fact that we have to deal with an acute infectious disease, the measures in vogue hitherto and to-day are directed toward alleviating the symptoms and supporting the strength of the patient until the time has arrived when the disease itself has run its course. The patient recovers or succumbs. Even to-day we have no specific remedy; we know that the prognosis in the form of disease which is the theme of this paper is much better than that of the pneumococcus form. We can do much for the patients. The general treatment is first directed toward eliminating the poison and, if possible, limiting the exudate. For this in all cases we give iodide of potassium in very liberal doses. We do this on the same lines that we would in a chest effusion or a subacute exudative process in the lung. We treat the fever with sponging. In two of the cases of this series the patients found great comfort in baths at 105° F. Especially was the benefit noted when chills and pains in the extremities were harassing symptoms. Netter mentioned this method of treating these cases in the recent International Medical Congress. Aufrecht has advocated warm baths. There are other minor methods which have been pursued in these cases; they include the ice helmet for the headaches; hypnotics for the delirium and the mercurial cathartics at regular intervals to counteract the constipation. In all this there is nothing but what has been done all along for these cases.

In this series of cases, however, we have pursued a method of treatment, that of repeated lumbar puncture which is directed more especially toward relieving symptoms due to the accumulation of exudate in the subarachnoid space and about the brain and cord. We certainly can justly trace symptoms, such as persistent headache, somnolence, coma, delirium, convulsions, to accumulation of fluid in and about the brain and cord, and to a certain amount of toxemia resulting from the absorption of inflammatory products. Repeated chills also may fairly be traced to purulent accumulation and renewed absorption of infectious material from the exudate. The mechanical relief of conditions of increasing pressure and diminution of gross amount of infectious material is certainly indicated in cerebrospinal meningitis of the variety described in this paper just as it would be in a pleurisy with effusion or a pericarditis, should symptoms of pressure arise. This was done systematically on indications in all the patients of this paper.

The lumbar puncture was carried out with all the details of antisepsis. Most of the patients were punctured three times in the course of the disease and one more frequently. There was no routine in the procedure, but each case was studied and when symptoms of pressure or accumulation of exudate appeared the puncture was made. The indications were continuous headache, accompanied by periods of somnolence and delirium, repeated chills with a sharp rise of temperature, an increase in the rigidity or opisthotonus, increasing or continued coma. If the immediate effects of puncture were favorable, the procedure was repeated if there was an exacerbation of the symptoms. If continued improvement followed puncture, the patient was no longer disturbed. In this conservative way, no ill effects of this method of treatment were observed.

In one patient the effects of puncture were remarkable; the patient upon exacerbation of symptoms requested that the procedure be repeated. The puncture showed that in some cases the fluid was under great tension and would flow from the cannula with a spurt so that quite a quantity could be withdrawn before the fluid ceased to flow freely.

In one case the primary lumbar puncture had no perceptible effect, the somnolence increased and the second lumbar puncture (15 c.c.) had only a very temporary effect, a dry tap followed; after a few days a fourth puncture, in which 10 c.c. of turbid fluid were withdrawn was followed by a gradual improvement in symptoms, after which the patient was not disturbed.

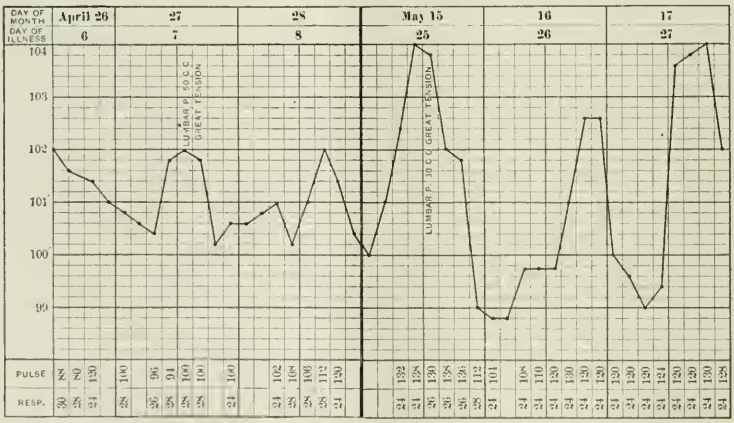
A second patient was very delirious before the first puncture: after puncture and withdrawal of 50 c.c. of turbid fluid, under great tension, the patient was quieter, slept well and became more rational; she continued to do moderately well until eleven days after, when she became more noisy, had severe headache and repeated chills. She was cyanosed; she was again punctured and 10 c.c. of turbid fluid was withdrawn. Her condition continued unsatisfactory; repeated chills supervened and she was again punctured and 30 c.c. of turbid fluid under great tension withdrawn. Improvement set in the next day the headache diminished and the child could move her head more freely;

she still had intervals of noisy delirium and some headache and pain in the back; she slept better at night. Nine days after this, pain in the head reappearing, with occasional noisy intervals and temperature persisting, a puncture was made and 16 c.c. of turbid fluid withdrawn. The patient immediately became brighter and continued to improve. On sudden rise of temperature fifteen days after, with accessions of headache, a tap was again attempted but nothing obtained.

Another case was that of a boy four and a half years of age in which at first there was a question as to the possibility of traumatic meningitis. After the first primary puncture of 25 c.c. of turbid fluid withdrawn under great pressure, the meningococcus being found, the case was diagnosed as cerebrospinal meningitis of the epidemic type. After this the boy, eight months of age, was not relieved by lumbar puncture. She was admitted in a comatose condition and the punctures and withdrawal of fluid did not relieve her nor clear up any of the symptoms.

Effects of Lumbar Puncture on the Pulse and Respirations.—If we refer to our records of the five cases, we find strangely enough that lumbar puncture, even when considerable amounts of fluid are withdrawn, has no marked effect on the respiration and pulse. In that of the comatose infant, although 12 c.c. at one time and 20 c.c. at another were withdrawn, the pulse and respiration continued in much the same irregular variations as before puncture. In another case the pulse dropped from 130, before, to 104 after puncture. It maintained this rate for fully 12 hours when it steadily rose to 120, 124 and 130 at intervals and continued

Fig. 2.



Female child eight years of age. Temperatures at two extremes of the disease. April 26–28, May 15–17. Chart shows the effect o lumbar puncture on the pulse and respirations. Recovery.

who had been stupid and irritable, became more rational, quieter and said he felt better. His movements, which had been involuntary, were passed voluntarily. Thirty days after admission, the temperature, headache and rigidity being present and there being complaint of chilly sensations, 5 c.c. of a turbid fluid were withdrawn. The temperature continued lower, symptoms improved gradually until complete recovery. This patient at no time after the first puncture presented anything but the milder type of disease. He would sit up at times and for days be quite rational. He complained principally of headache and pain in the neck. In another patient the principal symptoms were violent headache and pain in the back of the head and neck. There was delirium at intervals. Lumbar puncture relieved the headache and pain palpably. The infant, thus. Respiration was not markedly affected if at all. After subsequent puncture the pulse fell, but to a rate at which it had been recorded a day before the puncture. In another, at puncture, the pulse was 92, respiration 24. After puncture, respiration was 24, pulse 88 to 90. We cannot say more than that after repeated punctures in this case, the pulse fell in rate, though continuing very irregular. The fall extended over such a long period that the diminution cannot but be attributed to the subsidence of the process rather than to the immediate effect of puncture. In another case the pulse was 96 to 112 before and 90 immediately after puncture and in a few hours 100, ranging irregularly between 92 and 112. Respiration was 37 to 40 before, and 28 and 26 immediately after puncture, in six hours regaining a frequency of 30, dropping to 24 to 26.

Another puncture shows respiration 28 and pulse 100 before and 26 to 104 after puncture.

In another case of lumbar puncture, the respiration and pulse were as follows:

	Before.		After.	
	Respiration.	Pulse.	Respiration.	Pulse.
1.	28	84	28	100
	28	80	28	100
	28	92	28	100
2.	24	104	24	96
	24	96	24	98
	24	96	24	116
	24	108		
3.	24	102	24	104
	24	108	24	104
	24	112	24	100

It can only be said that the pulse is in some cases temporarily diminished in frequency, in others not at all, and that the respiration continues much the same. This is important because in those cases of cerebrospinal meningitis in which just before the fatal issue respiration ceases, whereas the heart continues its action, lumbar puncture will not aid us in restoring the respiratory function. If we look over the results obtained by repeated lumbar puncture, we can justly say that they have relieved symptoms. The relief seems to be more in the direction of a diminution of pain and a reduction of those symptoms which may fairly be traced to toxemia and mechanical pressure. At the same time, we cannot but feel that the withdrawal of an appreciable amount of any fluid from the spinal canal which contains bacteria and the toxic products of inflammation must be beneficial in the long run on the course of the disease. It is premature as yet to say to what extent the prognosis is favorably influenced by this procedure. It is, however, a method which it is certain will come more and more into general vogue, and take its place with aspiration of the pleural cavity as a curative method.

Case I.—Female, eight years, seven months. England. Admitted April 26, 1899. No tuberculous history. Other members of the family in good health. No other history as to diseases of childhood; has never had a cough but always delicate. Five days before admission was pushed while at play and struck the back of her head against a railing. There was no cut, but ever since she has complained of pain in the head. She has been restless at night crying out with pain. She has vomited all her food. Bowels constipated. Passed usual amount of urine. Has had no pain or discharge from the ears.

On admission it was found that her general condition was poor; tongue moist and coated; delirious; picks at her nose; pupils are equal in size and react to light; no paralysis; knee reflex exaggerated; tache cérébrale; ankle clonus of right ankle; rigidity of the neck; also tenderness; ptosis of the left eye; herpes of the upper lip; marked Kernig; lungs and heart normal; sounds forcible; liver and spleen negative; abdomen rigid; urine acid 1026; no albumin; no sugar. Expert examination showed double optic neuritis. Ears normal.

April 27th, lumbar puncture, 50 c.c. of a cloudy serum withdrawn under great tension. Fluid showed leucocytes and diplococci, intracellularis by stain and culture. After puncture patient was quieter and passed good night, being more rational. April 28th, second puncture, only 3 c.c. of fluid withdrawn; blood-count shows 15,600 leucocytes to cubic centimeter. May 5th, complains pain in left ear. May 8th, general condition not good; pulse intermittent; pain in right shoulder. May 9th, general condition worse; pain in right shoulder, no impairment of motion; hyperesthesia of skin; complains of severe headache and is very noisy at times. May 10th, condition bad; had repeated rigors, cold and cyanosed. Lumbar puncture, 10 c.c. of turbid fluid withdrawn higher up at a new site, the old puncture site being a dry tap. May 11th, rigor lasting five minutes followed by a temperature of 104° F. May 15th, repeated chilly sensations. Lumbar puncture, 30 c.c. of a turbid fluid removed. May 17th, condition improving; moves head without pain, but still has headache and pain in back of neck; is rational and delirious at intervals; sleeps well at night. May 19th, report of culture of above fluid showed diplococcus intracellularis; still has chilly sensations. May 23d, has intervals of quiet alternating with delirium; is especially noisy toward evening; cries out with pain. May 27th, lumbar puncture, 16 c.c. of turbid serum withdrawn. May 28th, general condition improved; is brighter. June 2d, blood-count, red 4,481,250, white 8,200. June 12th, lumbar puncture, dry tap. July 9th, expert examination of eyes by Dr. May; fundus normal, except that the margin of the discs are blurred, especially on the right side; no exudation; vessels slightly tortuous. July 23d, out of bed one hour. Aug. 16th, discharged cured.

Case II.—Female, nine years old, admitted April 29, 1900. Has had measles; no scarlet fever or pertussis or any pulmonary trouble; no history of ear disease. A few days before admission she fell, but had no bleeding; sixteen days ago complained of headache, vomiting; had chill followed by fever; chill recurred daily for ten days; no chills during past six days; headache is frontal and occipital; neck was painful and rigid; has had no cough; no eruption; has been rational. On admission the patient appeared dull and apathetic; slight left facial palsy; tongue deviates to

right; absence of knee reflex; weakness of left extremities; Kernig present; no ankle clonus; pupils react slowly; tache cérébrale. Lungs, equivocal signs. Heart, irregular in action; aortic regular murmur. Spleen, large.

April 30th, lumbar puncture for diagnosis. Discharge from ears. May 1st, more somnolent; Kernig more marked; abdomen retracted; delirious at night. May 2d, lumbar puncture, 15 c.c. withdrawn. May 7th, lumbar puncture, 10 c.c. of turbid fluid withdrawn. May 8th, by expert examination ischemic arteries of disc were found; no neuritis. June 10th, sitting up. July 24th, discharged cured.

Case III.—Male four and a half years old, admitted May 3, 1900. Has had measles and pertussis. Eight days before admission fell down striking the head behind the left ear; was stupid for two hours; no escape of blood from the ear, nose or mouth; no convulsions nor palsy nor vomiting; went to school and played for five days after, during which time he complained of pain at the site of injury; day before admission vomited; convulsions of the muscles on both sides of the body set in; there was fever and stupor, but no rigidity of the neck; some difficulty in swallowing.

On admission there was stupor and restlessness if disturbed; tenderness of the back of neck, but no rigidity of the neck. Pulse irregular. Organs negative; urine negative. Reflexes at knee absent; Kernig present; abscess on plantar surface of left foot. Expert examination of fundus of eye shows some exudation of discs, left more than right.

Lumbar puncture, 25 c.c. of a turbid fluid withdrawn under great pressure; diplococcus intracellularis by stain, abscess of foot contained diplococci and streptococci in short chains. After puncture child became quieter, said he felt better, asked for bedpan, whereas before this he had passed his movements involuntarily. May 7th, cover-glass spread from nasal secretion showed diplococci; some staining, others decolorizing with Gram. General condition good; has bilateral clonus; exaggerated knee reflex. May 13th, has had occasional headaches, but is improving; vomits at times. May 15th, scarlatinous erythema, twice in past three days. May 17th, repeated chilly sensations. May 18th, no Kernig. May 28th, feels chilly; slightly cyanosed; slight clonus. June 1st, lumbar puncture, 5 c.c. slightly turbid fluid withdrawn; spread shows diplococcus intracellularis. June 18th, systolic aortic murmur which is heard in vessels of neck. July 9th, examination of eyes shows descending neuritis of both eyes, with exudation in right. July 26th, discharged cured.

Case IV.—Male twelve years old, admitted August 21, 1900. Father has phthisis; mother is in good health. Boy has had measles. Three days ago complained of headache and vomited persistently. Fever followed and for two days he vomited his food. He was delirious, apathetic and complained of pain in his head and stomach. The delirium continued until admission.

On admission he was well nourished; delirious; tongue moist and coated; herpes labialis; marked rigidity of the neck with pain on motion; slight conjunctivitis; patellar reflexes absent; marked Kernig; tache cérébrale. Lungs, equivocal signs. Heart, apex forcible; pulmonary second sound accentuated. Spleen, not large. Abdomen, retracted.

August 22d, lumbar puncture, 40 c.c. cloudy fluid withdrawn. Two hours after puncture headache is less; pus cells in fluid, stain and culture, diplococcus intracellularis. August 23d, rigidity still present; knee reflexes absent; headache absent; erythema face and neck, chest and abdomen. August 24th, Kernig still present. August 25th, knee jerks present; rigidity of neck diminished; headache at night. August 28th, herpes labialis; optic discs show hyperemia. September 2d, Kernig present. September 3d, lumbar puncture, 15 c.c. fluid withdrawn, less turbid than previous puncture. Kernig less marked; left eye shows beginning neuritis. September 15th, lumbar puncture, 35 c.c. opalescent fluid withdrawn; pains in neck and back; tremor of face, tongue and hands; Kernig increased; rigidity of neck. October 1st, has had occasional headaches, especially in the afternoon; these headaches varied in severity; Kernig gone. October 19th, discharged cured.

Case V.—Female infant, eight months old, admitted October 26th. Family history negative. Six days ago mother noticed infant's left eye was red and had a purulent discharge; three days after noticed that the infant had fever and a discharge from the nose; two days ago had a convulsion which was not repeated; has since been in a semicomatose state; no cough; no vomiting.

On admission, general condition poor; infant is cyanosed; eyes are rotated upward; pupils react to light; there is a purulent discharge from both eyes; no nasal discharge; rigidity of neck. Lungs, equivocal. Heart, liver and spleen negative; abdomen distended.

October 28th, right-sided convulsions lasting fully an hour; rigidity of neck; reflexes exaggerated. Lumbar puncture, 2 c.c. turbid fluid withdrawn which showed diplococcus intracellularis in culture and spread. Pus from eyes showed diplococcus intracellularis in spread and by culture diplococcus decolorizing with Gram pure. October 29th, lumbar puncture, 12 c.c. viscid, flaky fluid aspirated, also cultivated pure found same diplococcus corresponding as above. Infant is comatose. Rigidity of neck; marked Kernig. Reflexes increased. October 31st, both knee-joints somewhat swollen and give a dry rubbing fremitus on manipulation. Pupils moderately dilated do not react. Diarrhea with green stools; discharging pus from eyes and nose. November

1st, convulsions repeated, involving whole right side; following this infant had right facial palsy; eyes rolled upward; slight opisthotonus. Lumbar puncture, 10 c.c. thick cloudy fluid; culture as above. November 2d, convulsions repeated. Infant became cyanotic, stopped breathing, but the heart's action continued beating 150 per minute; fairly regular; artificial respiration performed; breathing began again; died. Respirations ceased before heart.

66 East 58th Street.

DRAINAGE IN ABDOMINAL SURGERY.[1]

BY J. W. LONG, M.D.,

OF SALISBURY, N. C.;

PROFESSOR EMERITUS OF DISEASES OF WOMEN AND CHILDREN IN THE MEDICAL COLLEGE OF VIRGINIA.

MANY of the problems involved in abdominal surgery have been settled, not always in the same way, it is true, but by a general consensus of opinion which is the outcome of our gradually accumulated knowledge. Many of the procedures practised in abdominal surgery have been agreed on. For instance, every surgeon agrees and insists that his hands, instruments, the field of operation, etc., must be clean—surgically clean; and it doesn't matter whether a man believes in "bugs" or not, he says, "You must be clean;" nor does it matter whether he scrubs his hands until the superficial epithelium slips, dyes them and bleaches them in strong chemicals, or merely scrubs his hands and rinses them in alcohol, still he emphasizes the fact that one must be clean. Not only is cleanliness next to godliness in surgery, but it is godliness itself.

While some surgeons make a short abdominal incision and some make a long incision, all agree that the incision should be sufficiently ample to allow the operator to work easily and expeditiously. While some surgeons employ silk ligatures and sutures within the abdomen and others use catgut; some steam their silk fractionally, others boil it once only, still others do both; some sterilize their catgut by dry heat, others cumolize it; yet all maintain that whatever material is employed and by whatever process it is prepared, it must be sterile, non-irritating, easily absorbed, and of the smallest size commensurate with safety.

We all agree that loss of blood is the chief factor in the production of surgical shock. I dare not include in this category of agreements the various methods of closing the abdominal incision, for if the gentlemen who practise the different methods of closing the abdomen were to suddenly agree, we might be forced to draw the same inference that the new waiter did at the medical banquet, where, after several courses had been served, the new waiter said to the old waiter, "I believe these doctors are getting drunk." The old waiter replied, "I don't see any signs of it." The new waiter replied, "I don't either except that they are beginning to agree with each other."

Touching many other points there is also a general consensus of opinion. Why can there not be, then, some well-defined principles in the matter of abdominal drainage which can be settled. To this end I have invited the attention of this distinguished body. Ever since Robert Houston in 1701 incised the abdomen of Margaret Miller and left a "small tent in the lower angle of the wound," drainage has been considered a question of prime importance in abdominal surgery. Indeed, incision and drainage were about all the surgeons dared to do until the immortal McDowell deliberately removed a tumor from Mrs. Crawford in 1809.

That drainage is essential and desirable in some cases is evident, that it is unnecessary and undesirable in many cases is equally clear.

The Objects of Drainage.—The chief purposes for which drainage is employed are as follows: (1) To drain away existing septic material. (2) To afford an exit for the sepsis when the operator fears he has possibly infected his patient. (3) To provoke adhesions and thereby wall off weak spots from the remainder of the abdominal contents. (4) To keep the peritoneal cavity free of blood and other fluids. (5) To allow of a more certain knowledge of the conditions present in the abdomen. (6) Gauze drains are sometimes employed as tampons to control hemorrhage.

To Drain away Septic Material.—There can be no question of the propriety of drainage in those cases in which sepsis is already present. Its value has been emphasized many times in cases of suppurating appendicitis which may be taken as typical of septic cases. But it is to be noted, when we come to apply this rule of action to other cases presumed to be already septic, that the surgeon, who does not follow a routine, formerly drained many cases that he now feels safe in closing without drainage. By way of illustration, take the following recent case occurring in the hands of the writer:

Mrs. S., a very small woman, aged twenty-

[1] Read before the Southern Surgical and Gynecological Association, Atlanta, Ga., November 13, 1900.

three years, who forty-eight hours before she was seen had been delivered of an average-sized child. Conditions were only fair, pulse was 120, temperature 101° F. She was emaciated and the abdomen was greatly distended with an ovarian cyst. A few days' delay was advised. After ten days abdominal distention was increasing, respiration was beginning to be embarrassed. Contrary to the writer's usual custom he tapped the abdomen, drawing off thirty pints of heavy gelatinous fluid. This relieved the dyspnea but the evidences of sepsis continued. After a few days the patient having gained a little strength, she was taken to more comfortable quarters and the tumor removed. The tumor when removed weighed thirty-three pounds, which added to the thirty pounds removed at the tapping a few days previously made sixty-three pounds. The tumor and pregnant uterus probably weighed as much as the woman. The cyst was multilocular and contained many different kinds of fluid. Adhesions were numerous and evidences of a widespread peritonitis were present. Because of the bad condition of the cyst-wall a quantity of the fluid escaped into the abdominal cavity. The abdomen was thoroughly washed out and filled with the salt solution and the incision closed without drainage. The recovery was perfect. Formerly it would have been considered necessary to drain this case because of the sepsis and peritonitis. Nor is it necessary to always drain after removal of pus tubes even when the sac ruptures and the parts are bathed in pus, since it is well known that pus is frequently free from pathogenic germs. This is especially true in old abscesses. Even the presence of some forms of pathogenic germs, noticeably, the gonococci, is not an indication for drainage. The principle of drainage in septic cases is decidedly applicable when we invade the peritoneum through the vagina. Indeed, in these cases, as in suppurating appendicitis, the chief object is to drain the pus foci and serum distended tissues. Here we have ideal drainage, for gravity aids capillarity, and it is marvelous how quickly these patients often recover.

When the Operator Infects His Patient.—After the earlier operators lost their dread of opening the peritoneum, surgeons gradually learned that mere opening of this cavity was a perfectly safe procedure, provided the operator's hands and implements were sterile. In this day it is almost inexcusable for a surgeon to infect his patient, yet almost all of us say, "If we handle the parts a great deal it is better to drain"; unmindful of the fact that we are virtually admitting that we have probably infected our patient. With instruments, sutures and sponges thoroughly sterile, with our hands conscientiously scrubbed, washed in chemicals, and with the use of rubber gloves, prolonged handling of the parts ought not to be an indication for drainage.

However, the unexpected occasionally happens. Last month while the writer was doing a hysterectomy in a private house in a distant city, the patient suddenly stopped breathing, and she looked as if all the blood in her body had suddenly sidetracked itself into the capillaries and was going to stay there. It required prolonged efforts at artificial respiration, with the patient in the inverted position, to establish the respiratory function. But for the intelligent, faithful efforts of professional friends the patient would have died. The writer was kept busy trying to protect the open abdomen. Chloroform was the anesthetic being used. After this anesthetic episode everything went wrong, as they usually do when one thing gets awry. The outcome was that when the operation was finished we did not know whether the patient was infected or not. For fear that she was drainage was employed. The recovery was stormy, but satisfactory in the end.

To Promote Adhesions and Wall off Weak Spots.—The well-known property of the peritoneum to throw plastic lymph around any foreign body is often utilized when, after injuries to the bowel, ureter of other viscus, there is fear of leaking and consequent contamination. Here the gauze drain serves the dual purpose of isolating the vulnerable part and of drainage.

To Keep the Peritoneal Cavity Free of Blood and Other Fluids.—Just here is a point of departure. One set of observers cites the fact that blood or serum or any innocuous fluid when retained in the abdominal cavity makes an excellent culture medium and claims that the way to prevent infection is to keep the peritoneal cavity free of fluids. Even when hemorrhage has been controlled, advocates of this plan expect, in most cases, especially where many adhesions have been broken up, that there will be enough oozing to require drainage. They usually use a glass drain and empty it frequently with a long-nozzle syringe. Other observers take the position that the peritoneum is amply able to take care of any reasonably amount of oozing blood or, indeed, a large amount of other fluid, even when there is mild infection present, and they encourage this absorptive function of the peritoneum by leaving in its cavity a liberal quantity of normal salt solution, which is not only itself easily absorbed, but dilutes the oozing blood and thus renders it more readily absorbed. Those who follow this teaching close the abdomen without drainage no matter how many adhesions have been broken up or how much fluid is left in the peritoneal cavity.

To Allow of More Certain Knowledge of the Conditions Present in the Abdomen.—This argument is used particularly in favor of the drain-

age-tube in cases in which there are great fears of hemorrhage. It must be conceded that hemorrhage occurring within a few hours after the operation may be detected by means of the drainage-tube and syringe. The same is true to a less degree of the gauze drain.

The objection to this argument is that in the vast majority of cases it is unnecessary to inspect the abdominal cavity to see if there is hemorrhage. The use of suture material that will not readily break or untie, with careful inspection of every possible bleeding-point, ought to insure against hemorrhage; certainly this is true in all cases in which the tissues are not softened by sepsis or malignancy.

Gauze Tampons.—There is a variety of circumstances under which it is expedient to pack a bleeding-point with gauze tampons to control the hemorrhage. In these cases the gauze, of course, also acts incidentally as a drain.

Histology and Physiology.—Many of the reasons advanced in favor of drainage were promulgated before the histology and physiology of the peritoneum were understood. Wagner in 1877 was the first to demonstrate the wonderful ability of the peritoneum to absorb fluids, even as much as the entire weight of the animal being absorbed in twenty-four hours. Muscatello in 1895 proved that, while there were no stomata between the peritoneal endothelium cells, fluids and minute foreign bodies passed between the endothelium of the diaphragmatic peritoneum by a retraction of the cell-protoplasm and were then taken up by the open spaces, found only in this portion of the peritoneum, and passed on into the lymp-circulation. This observer demonstrated a normal intraperitoneal current capable of carrying fluids and small bodies to the diaphragm, and this, too, irrespective of position although gravity has a marked influence on the current. It also has been shown that the leucocyte is the principal bearer of foreign particles along the highway just described.

Another fact pertinent to the question is that the leucocytes and other factors producing this intraperitoneal current bear off pathogenic bacteria along this wonderful highway as readily as they carry innocuous substances, provided the enemy is not too numerous or too virulent. These facts open up to view the surprising capabilities of this highly vitalized membrane, and the abdominal surgeon should doff his hat to his ablest ally—the peritoneum.

Objections to Drainage.—Excluding cases of acute suppurative infection, such as appendicitis, pelvic abscess, that can be reached through the vagina, and wide-spread general peritonitis, drainage is objectionable for many reasons. Among them are the following: (1) It is deceptive. The writer has tried all kinds of drainage and found them unsatisfactory. Drainage is not a guarantee against infection—the even-present menace to the patient; in fact, both gauze and the glass tube constitute an additional source of infection. (2) Cases not drained do better. The observation of any considerable number of cases will demonstrate this. A smaller percentage of the patients become infected; they suffer less nausea, less pain, require less morphine, have less tympanites; the bowels are more easily moved; the mortality is lower, and, in a word, they do better than cases that are drained. (3) Drainage is neither scientific nor workmanlike. I say this with an apology and with all due defference to those distinguished gentlemen present who drain most of their cases.

Take a case of large myoma or pus tubes with adhesions. To drain such a case is to say in substance to the patient, "We cannot open your abdomen, remove the abnormal growth, separate the unnatural adhesions, and close your abdomen without leaving your peritoneum in a condition that requires an open door." The "open-door" policy is all right for China, but not for the peritoneum. The presence of a drain is a tacit admission that we have left something undone that we ought to have done, or that we have done something that we ought not. Even in a case of suppurative appendicitis or pelvic abscess, if we could enucleate the sac in its entirety and without contaminating the surrounding tissues, just as we do a simple pus tube, there would be no need of drainage; but since this cannot be done, we must content ourselves with less complete work and leave Nature to finish the job. Joseph Price, who is known as an advocate of drainage in certain cases, is quoted as saying, "Drainage is an evidence of incomplete work." In a word, when we drain we do so because we cannot do better.

VERTIGO; A STOMACH LESION.[1]

BY MARTIN A. H. THELBERG, M.D.,
OF NEW YORK.

It may seem preposterous for one, who can lay no claim as a neurolgist, to present a paper on a subject, gastric vertigo, about which there exists so many differences of opinion. As, however, one of the aims of our Association is to encourage discussion relative to the various subjects, that come to our notice, and as I have seen numerous cases of vertigo in which very painstaking diagnoses and subsequent successful treatment have been sufficient to dispel any doubt as to the etiology, I take pleasure in offering this paper in the hope by bringing forth the theories, experiences and criticisms of my confrères.

[1] Read before the Alumni Association of the City Hospital, November 14, 1900.

Under the symptomatology of vertigo is included not only the "turning around" that the word *-vertere)* signifies, but also the various symptoms, familiar to us all since childhood, coincident with turning. The vertigo proper may indeed be of many forms and varying in degree. It may be *scotodynia*, where the sight is obscured and the patient falls from a complete loss of equilibrium and usually also of consciousness, or *gyrosa*, when either the patient, or things about him seem to revolve and where the sense of equilibrium is more or less affected. In other instances the floor, or pavement, seems to rise, or sink, or a giddy, dizzy "lightheadedness" is experienced with darkness and occasional sparks, or flashes of light before the eyes, causing the patient to grasp for support for fear of falling. Usually this sensation is of short duration, but at other times it is either frequently recurring, or else more or less persistent, so that, even while lying in bed, a sensation of sinking, revolving or rocking is experienced, which is increased by the least movement of the head. These patients in my experience, at least, have proven the most intractable to treatment; as the psychical state, with fear of renewed attacks, is far worse than the vertigo itself and is one of the most potent etiological factors for renewed attacks. Another familiar example of the influence of fear upon the equilibrium is the dizziness, or actual vertigo of some people on looking down from some high place, as a tower or cliff.

In almost every instance of vertigo we will observe more or less pronounced nausea, or often even actual emesis. The nausea, if at all persistent, is indeed a most distressing symptom, especially as it is usually associated with cold sweats, fluttering of the heart, tinnitus, pyrosis, and worst of all, fear of approaching death from apoplexy, or cardiac disease. The heart indeed almost always acts very badly in these cases—it is weak, intermittent, at times to such an extreme that one cannot but share to some degree the patient's alarm. The patient feels confident that the end has come, often presses his hand over the precordia, proclaiming that the heart has stopped or ruptured, and afterward describes the sensation as one of extreme pain and compression of the heart. These symptoms are, however, relieved by emesis and eructation of gas and the patient, who has been cold and livid, breaks into a profuse perspiration. Usually more or less prostration and irregularity of heart action persist, according to the severity and number of attacks.

In glancing over the literature on the subject, one cannot help but feel perplexed at the differences of opinion regarding the etiology of what Trousseau so vividly describes in the *Clinique Médicale* as "vertigo e stomacho læso," and known amongst the Germans as "Magenschwindel." Before citing different authors on this subject it may be well to define the author's idea of this affection as follows: "Vertigo in a person without any obtainable evidence of disease of the apparatus of equilibrium, or audition, or vision, or the brain, especially when the attack is traceable or subsequent to some dietetic indiscretion, or gastro-intestinal disorder and when curable by appropriate regimen and treatment directed toward the correction of such, digestive disturbances."

Gowers says, in his Diseases of the Nervous System, "I do not think that it is quite certain that there is such a thing as definite vertigo of purely gastric origin. Thirty years ago 80 per cent. of cases of giddiness were supposed to be due solely to the stomach. But we now know that in 90 per cent. of the cases a morbid state of the labyrinth is the real cause of the vertigo. It is possible, that in the small remainder, of apparently stomach giddiness, there is some other influence that is the real cause, *e.g.*, a morbid state of the semicircular canals exists which, causing no auditory symptoms, is not to be detected save by its effects."

S. Weir Mitchell, in Pepper's System of Medicine, says that "Trousseau certainly misled the profession as to the frequency of this (the gastric) form, but he did little more than represent the popular medical views, and we may now feel sure that a good many so-called gastric vertigoes are due to lithemia or to trouble of eye or ear. As a rule, such an attack need cause no uneasiness as to fatal result, but, unless the case be handled with skill, it is apt to repeat itself, until what I have called the *status vertiginosus* is created.

Ramskill, in Reynolds-Hartshorne's System of Medicine, says: "The most common and most tractable eccentric variety (of vertigo) arises from disorder of stomach, or of functional derangement of the liver and upper part of the alimentary canal. From its violence it suggests the idea of imminent danger. Chronic stomachal vertigo is of very common occurrence, and one often supposed to indicate the commencement of congestion, of organic disease of the brain, or of threatened apoplexy; and the treatment which has been adopted under such erroneous diagnosis has only served to render the vertigo permanent." Dana, in the Text-book of Nervous Diseases, says: "Stomachal vertigo is the name given to a very severe form of reflex vertigo. It occurs generally in persons whose stomachs are overloaded and whose digestion is paralyzed by its load. It is accompanied by loss of consciousness." Collins, in his work on Treatment of Nervous Diseases, says: "Such vertigo is much less common than is usually supposed." Flint, in his Practice of Medicine, says: "In a certain proportion of cases, the attacks appear to be incident to dyspepsia. This causation, however, is certainly not as

constant as it is regarded by Trousseau." Loomis, in Practical Medicine, says: "Gastric vertigo is the most common and is an almost invariable attendant on dyspepsia. It is often so severe and sudden in its onset that the patient thinks he is soon to have a stroke of paralysis. The mental state is often deplorable and true melancholia may ensue." Osler, in Practice of Medicine, says: "This variety of vertigo (gastric) is much less common than Trousseau's description would lead us to believe." Hemmeter, in Diseases of the Stomach, 1900, says: "This affection occurs in neuropathic patients with hyperacidity and is associated more often with gastric neurosis than others. It is a more frequent complication of hyperchylia than is generally known. Treatment of the fundamental gastric disease removes the vertigo, as a rule."

Einhorn, in Diseases of the Intestine, 1900, says: "Leube describes several cases of intestinal vertigo, due to pressure existing in the lower end of the bowel and caused by irritation by fecal matter or a large amount of gas, or even the examining finger, from which he reasons that the vertigo is reflexly from pressure upon the hemorrhoidal plexus of the sympathetic," and in his Diseases of the Stomach, says: "In some instances of chronic gastric catarrh there appears a dizzy feeling which is occasionally so severe that patient cannot occupy a standing position, but has to sit down or lie down." Ewald, in Diseases of the Stomach, says: "Trousseau deserves the credit of having first directed attention to the relation of those attacks of vertigo with chronic catarrhal gastritis."

Leube, in his Ueber den Magenschwindel, Ziemssen's Handbuch d. spec. Path. and Therap., Vol. II., mentions that gastric vertigo may occur in some persons after the ingestion of certain foods.

As can be seen from these citations we have, indeed, some of our best observers at variance, and we must consequently rely exclusively upon our own conclusions, which, after all, is the only satisfactory way when we conscientiously study our cases and employ due logic in our diagnoses. Bearing in mind that vertigo undoubtedly can result from disease of the semicircular canals, cerebellum and nerves of Cyon, as well as from errors of refraction and the ocular muscles, and that, furthermore, polypi or disease of the external or middle ear or of the Eustachian tubes or the larynx may be the etiological factors as well as tumor or disease of the brain, epilepsy, neurasthenia or hysteria, we ought certainly to be able to diagnose the case by due care and thoroughness, without fear of contradiction.

In the diagnosis of these cases it is naturally of the utmost importance to first and foremost obtain as complete a history as possible, including previous attacks, possible, ascribable, immediate cause, existence of disease of ear, eye, nose or throat, brain, heart or digestive tract. By following this with otological examination and tuning-fork test, Menière's disease is practically excluded. Simple tests as to the condition of the ocular muscles, accommodation and vision, followed by Pulitzer's test, rhinological and throat examination, neurological examination as to knee-jerk, ataxic symptoms, sensation and motion, will by exclusion practically leave digestive disturbances as the primary cause. In confirmation of this the stomach will in the majority of cases be found considerably distended, tympanites, pyrosis, colic and distress after eating will usually be complained of, as well as constipation or looseness of the bowels. The especial attack will generally be ascribed to something eaten. One of my patients had a very severe attack after eating broiled lobster, another after a table d'hote dinner, still another had vertigo of the worst kind after drinking a glassful of claret or sauterne, although other wines caused no distress. Ice-cream, liberal indulgence in coffee and cakes (in German fashion), plum-pudding, etc., may be enumerated as other causes.

The diagnoses given by previous medical attendants have in the writer's cases varied between apoplexy and cardiac disease. In not less than two cases in my immediate neighborhood were the patients and their families living in constant dread of sudden death, as other physicians had pronounced previous attacks as slight strokes.

In regard to the mechanism of *vertigo e stomacho* the writer is of the opinion that this symptom is brought about by either, or all of three causes, to wit: (1) Reflexly through direct irritation of the gastric branches of the pneumogastric and thence by the lower cervical ganglion to the vasomotor nerves of the vertebral artery, which supplies the internal ear. (2) By toxemia from amulon, and other ptomaines, nicotine, alcohol, reabsorption of bile, the toxins of the infectious diseases, etc., etc. (3) By direct pressure upon the heart through distention of the stomach and intestines by gases, resulting principally from so-called amylaceous indigestion and hyperchylis.

Although it has not been the writer's good fortune to meet with a single case of purely Menière's disease, still I do not for a moment doubt or dispute that disease of the semicircular canals, nerve of Cyon, or the apparatus of equilibrium generally, will cause vertigo. The writer's contention is only that actual disease of this kind is of far less frequency than irritation of the centers controlling equilibration, and, from the successful treatment of over 20 well-marked cases of this kind (besides several less typical ones), I feel convinced that gastro-intestinal disorders supply the irritant in the majority of instances by either or all of the afore-named three ways.

The treatment that in the writer's expe-

rience has proven curative in the most alarming, as well as recurring cases, is the correction of the gastro-intestinal disorder. This has in most of my cases been accomplished by the administration of a glass or two of hot water half an hour before meals, with some sodium bicarbonate before breakfast, and from three to four grains of diastase with each meal, preferably in combination with $^1/_{20}$ to $^1/_{10}$ gr. strychnine and in some instances a pepsin ferment. The patient should also be instructed as to the theories and importance of thorough mastication and appropriate diet. As the result of previous experiences, it has also become the writer's routine to explain, in as concise and plain terms as practicable, to the patient the existing condition, thereby preventing unnecessary anxiety, as well as further attacks.

My conviction, gained from the treatment of a good many cases of this kind, is, that the *status vertiginosus* as a sequence of gastric vertigo only proves the lack of knowledge of the chemistry and physiology of digestion, or of inappropriate treatment, on part of the attending physician.

205 West 105th Street.

AN INTERESTING CASE OF SPLENIC ANEMIA.[1]

AN INTERESTING CASE OF SPLENIC ANEMIA.*

BY HERBERT MAXON KING,
OF GRAND RAPIDS, MICH.

WITHIN the last year or two considerable attention has been given to the pathology and clinical history of a condition characterized by a marked enlargement of the spleen associated with a progressive anemia, usually terminating in death. Investigation to the present time has seemed to identify in this condition a pathological entity which, for convenience and to avoid as far as possible annoying confusion in nomenclature, is generally understood by the term "splenic anemia." Among several other terms used to designate the same disease "splenic pseudo-leucemia" and *"spleno-megalie primative"* are perhaps most common; both, however, fail to convey a clearer meaning, and are even more ambiguous, while the latter has the additional disadvantage of being recently employed to designate a condition quite distinct, pathologically, from that which is usually understood by splenic anemia.

In November, 1899, B. W. Sippy published in the *American Journal of Medical Sciences* a critical summary of the literature on splenic anemia; and in the following January an interesting article on the subject by Osler appeared in the same journal. Sippy found the number of cases, clinically recognized, up to the time of his writing, not to exceed twenty-five. A number of cases have been reported since the appearance of his paper, but the total is still comparatively small.

[1]Read before the Academy of Medicine of Grand Rapids, Mich., October 16, 1900.

David Bovaird, Jr., in the *American Journal of Medical Sciences*, October, 1900, gives a very interesting report of two cases similar in many respects to splenic anemia, but which have pathological distinctions which, he considers, place them in a group by themselves hitherto unrecognized and which he terms "primary splenomegaly."

The following case, seen through the courtesy of Dr. J. A. McColl, is clinically one of splenic anemia, and, while fairly classical in essential features, it differs sufficiently in minor points to be of considerable interest. It will be seen that the blood-changes which we found in our case are far more marked than those generally reported and would in the absence of the enormous splenic hypertrophy be sufficient to place it within the category of the primary anemias.

Unfortunately, we were unable to secure autopsy in this case, indeed the patient left the hospital and refused to see her physicians several months before her death, and consequently this report is of necessity incomplete, being limited to the clinical aspects of the case alone.

Photograph showing area of cardiac dulness, apex beat, outline of splenic border and crest of ilium.

In October, 1899, Dr. J. A. McColl kindly asked me to see the subject of this report, a patient who had but lately before come under his observation. The case was found, upon superficial examination, to be of such interest that the patient was admitted to one of the free beds at Butterworth Hospital, where in due course the following history was obtained:

A woman, forty years of age; born in Yorkshire, England, where she lived until adult life; she has since lived in Michigan. She could give no account of her father. Her mother died at the age of fifty-eight years of an "obscure trouble in the left side" (an interesting fact in view of the present case). She has one living sister, older than herself and in good health, and has never lost either brother or sister. At nine years of age patient began work in a factory in Yorkshire, where she remained until her marriage at the age

of seventeen. Menstruation was established at fifteen years, has always been and still is regular, lasting three of four days with some dysmenorrhea. At eighteen years she gave birth to a healthy child, who at time of this examination is living and in good health. A second child, who died soon after birth, was born in her twenty-third year. Her husband died from an accident at forty years of age, and in her thirty-seventh year she married a man much older than herself with whom she is at this time living. She has never been in a malarial district and gives no suggestion of syphilitic taint. She is evidently a woman of ordinary intellectual capacity, but is profoundly ignorant.

She states that until July, 1899, she was always perfectly well; at that time she was suffering from an obstinate constipation for relief of which she took two pills from a sample which had been left at her door as an advertisement. She dates her illness from this occurrence, following which she had a severe diarrhea, passing at times considerable blood, which persisted for three weeks. She then partly recovered and undertook to proceed with her household duties. Following a day's hard work she had a relapse, from which she has never recovered and chiefly for which she consulted a physician. Her more intimate friends say that for a number of years she has had a "peculiar, pale yellow color." She had probably lost in weight, but at the time of examination and subsequently as long as she was under observation, was not emaciated. She complains of griping pain in the abdomen, somewhat paroxysmal, attended with diarrhea and extreme prostration.

Examination.—As above stated there is little or no emaciation. The face wears an anxious expression. There is a slight puffiness under the eyes and a perceptible edema of the lower extremities. The skin presents a peculiar, yellowish pallor which characterizes primary blood-lesions. The abdomen is not prominent. The vessels in the neck pulsate markedly. The conjunctivæ are very pale and have a fatty appearance. The mucous membranes are very pale and the teeth badly decayed. There is slight dulness and faint wheezing râles at apex of the left lung. The apex beat is 3½ inches to left of median line in fourth interspace. The area of cardiac dulness is not enlarged. There is a noticeable murmur, both systolic and diastolic in rhythm, beginning before, and persisting after, the second sound, with a maximum intensity at the second *left* interspace and sternum, diffused over the whole superficial heart area, but not heard behind or along the vessels of neck. The mobility of the left chest is restricted with upward displacement of the viscera and downward excursion of left diaphragm limited to level of fifth rib.

Palpation of the abdomen does not elicit pain. It is slightly tympanitic to percussion on the right side; the left lobe of liver is palpable, but the organ as a whole is not perceptibly altered in size, shape or feel. The kidneys are not palpable. The spleen, enormously enlarged (see photograph), retains, however, the contour of a spleen even to the notch in anterior border. It fills nearly the whole left half of the abdomen, the anterior lower border falling below the crest of ilium in ordinary posture, while the right anterior border is palpable to the median line. Palpation of the mass does not elicit pain. The pulse is full, soft, rather "bounding" in character, and 104; temperature, 100.2° F.; respiration not markedly disturbed. An occasional cough is productive of slight mucous expectoration, containing no tubercle bacilli. The urine is of low specific gravity; deficient in the salts and fails to respond to the tests for albumen, peptones, sugar, bile and indican, while the sediment contains no formed elements of significance.

The peripheral blood was examined October 6th and again October 12th. The splenic blood obtained by aspiration was studied qualitatively a day or two subsequently and found to differ in no important feature from the peripheral blood.

Following is the report of the blood examinations made October 6, 1899:

Quantitative.—Red corpuscles, 950,000; leucocytes, 780: hemoglobin, 15 (Von Fleishl); color index, .83.

Differential Computation of Leucocytes.—Small lymphocytes, 22 per cent.; large lymphocytes, 5 per cent.; polymorphonuclear neutrophiles, 55 per cent.; eosinophiles, 0; transitional forms, 3 per cent.; myelocytes, 15 per cent.

It will be seen that with the exception of the myelocytes, a normal relation exists between the varieties, the greatly reduced total number of leucocytes per cubic millimeter is not unusual in profound primary anemias.

The large percentage of myelocytes if persistent would point to a myelogenous leucemia notwithstanding the low total of leucocytes, but subsequent examinations failed to sustain this large percentage for which I cannot satisfactorily account at this time.

Qualitatively, the blood evidenced destructive changes of a character more profound than I have ever remarked in any condition except that of pernicious anemia.

There was marked poikilocytosis. Sippy states that in splenic anemia "there is no marked alteration in the form and size of the red corpuscles. Poikilocytosis has not been recorded. . . . Nucleated red corpuscles have not been observed."

In our case there was not only marked poikilocytosis, but also polychromatophilia, macro- and microcytosis, while a little more than two nucleated red corpuscles were counted to every 100 leucocytes; these were mostly megaloblasts, some of the nuclei of which presented beautiful kariokinetic figures.

On October 12th blood examination resulted as follows:

Quantitative.—Red corpuscles, 875,000; leucocytes, 3,150; hemoglobin, 15 (Von Fleishl); color index, .86.

Differential Computation of Leucocytes.—Small lymphocytes, 22½ per cent.; large lymphocytes, 8 per cent.; polymorphonuclear neutrophiles, 61 per cent.; eosinophiles, 0; transitional forms, 4½ per cent.; myelocytes, 4 per cent.

Qualitatively the changes in size, shape and color reaction were identical with those of the former examination.

In counting 200 leucocytes there were noted nucleated red corpuscles as follows: Normoblasts, 2; megaloblasts, 13; and other anomalous forms, 5. As above stated the splenic blood differed in no essential feature from the peripheral blood.

A few days following the last blood examination the patient left the hospital and was not seen again by either Dr. McColl or myself. The case terminated fatally the following December and autopsy was unobtainable.

The points of interest in the case rest chiefly upon its evident close relation to splenic leucemia on the one hand and pernicious primary anemia on the other; but our study of the blood, with that of the clinical history of the case in general, convinces us that it belongs to the group of obscure toxemias most conveniently included under the head of splenic anemia.

MEDICAL PROGRESS.

Suprarenal Gland Extract and Epistaxis.—Lewis S. Somers (*Phila. Med. Jour.*, March 2, 101) discusses the dangers of sepsis from the use of the extract of suprarenal gland in epistaxis as the drug is usually employed. There is no question but that the drug possesses qualifications rendering it superior as a local hemostatic and vasomotor constrictor to all other remedies. The writer has found that by adding one grain of pure carbolic acid to a dram of sterile water containing ten grains of adrenal extract and then filtering through paper, a solution is obtained that retains the maximum efficiency and is both sterile and permanent. He has used this formula for some time and has always found it reliable. This solution is improved, however, by adding to it a sufficient quantity of cucain to make a one,- two,- or three-per-cent. solution. By this addition an anesthetic action is obtained as well as the full vasoconstrictor action of the extract of suprarenal gland. The method of using this solution in an acute case is to place a pledget of cotton saturated with it over the point of bleeding, if possible, for a few minutes, then thoroughly spray the nostril with the same solution, and, finally, to cleanse the parts with a simple alkaline solution. In a chronic or persistent case it may be necessary to place a pledget of cotton saturated with the adrenal solution loosely in the nostril every night, or once or twice a day, or to drop a few drops of the solution in the nostril twice a day. The writer reports a few cases illustrating the efficiency of this remedy and the different ways of using it.

Paralysis Agitans.—Most forms of tremor can, according to J. M. Taylor (*Jour. of Nervous and Mental Dis.*, Mch., 1901), be benefited by regulated and systematized movements such as shall reëstablish the greatest elasticity in the contractured tissues. Passive extensions and flexions should be followed by active similar motions. The most important movements to overcome the milder forms of tremor, as the senile form, are slow, full, forcible extensions. At the same time the respiratory capacity should be constantly exercised by lung gymnastics.

Brain Abscess and Empyema.—Brain abscess from pulmonary disease is not very common. While an abscess may be caused by disease of either lung or pleura, it more usually results from the former. T. A. Clayton (*Phila. Med. Jour.*, March 2, 1901) reports the case of a man twenty-two years of age, who, after an attack of malaria contracted in Cuba, had a bad empyema. After an illness of two months, during which time paracentesis was performed twice and a resection of part of the seventh rib was done, and later a resection of portions of the fifth, sixth and seventh ribs, the patient recovered from the empyema. But about three weeks later the patient returned complaining of having had a chill, with headache, high fever, nausea, and profuse sweating. There was a second chill with the accompanying symptoms, and since then he had had an intense pain in the head, extending all over the cranium and down the back of the neck. Whenever food was taken, vomiting occurred. He was constipated. Temperature was 103.2° F., pulse 120, respirations 24. His face was flushed and had an anxious expression upon it. His tongue was clean. The usual remedies for headache failed to relieve. It was thought that his condition was due to a reaccumulation of pus in his chest. His headache continued and the nausea was continuous. He became delirious, refused nourishment, and sweated profusely. On the fifth day his temperature rose to 104.4° F., there was for the first time rigidity of the neck, and he died. During this attack there was no strabismus, no paralysis, no inequality of the pupils. The autopsy showed multiple abscess of the brain, a very small area of basal meningitis, parenchymatous nephritis and beginning degenerative change in the liver-cells. From the findings of the autopsy Clayton thinks that there is no reason to doubt that the abscesses in the brain were metastatic from the old empyemic fistula. He is unable to explain why the abscesses should form in the white matter of the brain and not in the spleen, liver, kidneys, etc. The writer cites 58 cases, in literature, of brain abscess resulting from primary lung disease, showing that empyema is only second to bronchiectasis as a cause.

Cysts of Ovarian Remnants.—H. Ehrenfest (*Centralbl. f. Gyn.*, Feb. 23, 1901) says that the question is still open whether or not the patient is served or damaged by leaving behind ovarian tissue in certain operations.

Although the formation of cysts in these stumps is not any more frequent than that of carcinoma in the stump of the cervix after supravaginal amputation, it is common enough in literature to render the consideration of total ablation of the ovary pertinent. A safe principle will be that, when an ovary is cystic, or is part of a diseased appendage or lies in a diseased peritoneal pouch, a complete extirpation will be wise.

Sensitiveness of Abdominal Cavity.—K. G. Lennander (*Centralbl. f. Chir.*, Feb. 23, 1901) has been making observations on the nervous supply of the abdominal parieties, peritoneal investment and viscera with special reference to its bearing on operations on the organs and wall and local and general anesthesia for them. He arrives at the following conclusions: (1) The peritoneum parietale is rich in the nerves of *pain* sense; (2) the peritoneum viscerale, gastric and enteric canal, gall-bladder, kidneys and liver are bereft of nerves for the senses of *pain, touch, heat* and *cold,* so far as his present observations have indicated. As a very valuable means of anesthesia and a substitute for either pure local or pure general anesthesia, he has found combination of both a very valuable procedure. He has found that an application of local anesthesia by the method of Schleich and just enough chloroform or ether to stop vomiting will permit any procedure to be carried on.

General Paresis and Brain Tumor.—Wharton Sinkler (*Phil. Med. Jour.*, March 9, 1901) remarks upon the frequency with which patients having general paresis have symptoms which simulate localized disease of the brain, such as brain tumor, and says that the convulsions which often occur as a late symptom of general paresis frequently begin in or may be confined to one arm. These convulsive seizuers sometimes are almost typically Jacksonian in character. As the paresis progresses these seizures may involve the whole side of the body and there may be unconsciousness for a variable length of time. Then, too, after a convulsion, paralysis may be more or less complete in the arm or whole side for several days. When the right side of the body is the one affected aphasia may be present, either transient or more or less permanent. The differentiation between general paresis and brain tumor, when the symptoms of the former condition are not marked is rather difficult. This is especially so when the mental symptoms of paresis are not pronounced. The writer reports in detail two cases illustrating the similarity between the two conditions, general paresis and tumor or other gross lesion of the brain.

Appendicitis Simulating Strangulated Hernia.—J. B. Pike (*Lancet,* Feb. 23, 1901) reports, on account of its rarity and highly instructive diagnostic value, a case of chronic appendical abscess simulating strangulated inguinal hernia. The well-nourished, thirty-five-year-old man was seen first by him in consultation Jan. 7, 1901; had had a severe attack of abdominal pain, nausea and vomiting, as a recurrence of several previous mild attacks of the same kind and as a sequela noticed six months later a right inguinal swelling disappearing when lying down except when turned on the right side. Jan. 5th, a violent recurrent attack appeared; on the 6th, with obstruction and stercoraceous vomiting; on the 7th an enema produced a passage of gas, fluid feces and scybalæ. That night in the dorsal decubitus position he showed slight general abdominal distention and tenderness, fulness in the right iliac region, an oblong mass in the inguinal canal free from impulse on coughing, and obliteration of the external abdominal ring. Under ether the ring could be outlined, but the character of the canal contents could not. The patient died before any operation could be performed. At the autopsy were found an old appendical abscess with a prolongation into the inguinal canal, a perforated appendix, a perforation in the abscess wall and peritonitis. Whether any one could have made the diagnosis or will make it under such data is doubtful, but the case is extremely instructive as showing a remarkable condition.

Hernia in the Aged.—C. S. Brebner (*British Med. Jour.*, Feb. 23, 1901) reports for Mr. Plummer a case of strangulated oblique hernia in an eighty-year-old man. The hernia was of twenty years' standing, had always been readily reducible until the morning of his admission to the Edinburgh Royal Infirmary, on December 22, 1900. No truss had been worn at any time. On admission he presented great feebleness of old age, marked muscular tremors, very like those of paralysis agitans, a large scrotal right oblique inguinal hernia, hard, tense and tender, absolutely irreducible, unaffected by taxis and enemata. Defecation had last occurred December 21, 1900. His skin was prepared for operation and ice applied locally. Under chloroform part of the rupture returned spontaneously, but the balance persisted. Ball's operation for radical cure was done and the bowel, found to be universally healthy, was all returned into the abdomen. Excepting a rise of temperature during the first three days and restlessness the course was straightforward and primary union resulted. The patient was discharged on the 8th of January in excellent local and general condition. Mr. Plummer employs Ball's operation in the aged on account of its rapidity and he usually does not cut the ligature about the sac short, but passes an end through each pillar of the external ring, thus checking any untwisting of the sac and the need of a deep ligature as recommended by Ball.

Normal Salt for Gonorrhea.—Freedom from complications is still considered of far more importance than short duration, the aborted cases often retaining the attenuated germ in the tissues ready to take on virulent growth at a favorable opportunity. The gonococcus is a frail germ not capable of growing at above 100.4°F., and having its virulence and reproductive power destroyed at 103°F. Therefore C. E. Woodruff (*Med. Rec.*, Mch. 16, 1901) argues that if hot solutions can be introduced into the urethra without injuring the tissues, the disease will be cured. But as plain water is irritating to all mucous and serous membranes, he uses normal salt solution. Irrigations of this every one or two hours remove the poisonous toxins of the gonococcus, destroy the virulence of the germ, and soothe the urethra. Ninety-eight cases treated show cure in from two days to four weeks, but usually in ten to fourteen days.

Formaldehyd versus Sulphur Fumigation.—To test the comparative value of sulphur and formaldehyd, R. G. Schnee (*Cleveland Med. Gaz.*, Mch., 1901) used a room with 1,003 cubic feet space, containing carpet, bedding and furniture. The windows and doors were sealed moderately well, but cracks in plaster and baseboard were left alone. Twenty-four-hour bouillon cultures of typhoid, diphtheria and staphylococcus aureus germs, and five-day cultures of anthrax rich in spores were used. Cover-glass smears were dried and wrapped in one layer of sterile lens paper, and others in two layers of cotton comforter. Cotton threads were soaked in the cultures, dried, and placed in short open tubes of large caliber and similar threads in one layer of cotton comforter. Twenty-four-hour cultures on Loeffler's blood-serum were exposed with cotton plugs removed. Duplicates were exposed in all cases, and control cultures kept. Two experiments were made with 3 and 6 lbs. respectively of sulphur in a dry atmosphere, and of the same with the objects moistened with sterile water. The room was not opened for sixteen hours. With formaldehyd, Parke, Davis & Co.'s generator with 150 c.c. formalin were used dry and moist, and the test was also made with Moffat's generator, dry and moist. Sulphur in 6 lb. quantities was nearly as efficient as dry formaldehyd, but the latter when moist was more effective. The objects wrapped in cotton comforters were disinfected by neither. When large rooms are to be fumigated, paraform, 60 grains, may be dissolved in 150 c.c. formalin containing borax, this amount disinfecting 2,000 cubic feet. A good enough apparatus consists of a 1,000 c.c. Bohemian glass flask with a thistle-mouth funnel reaching nearly to the bottom and a conducting tube to carry the vapor through the key-hole. This, heated with a Bunsen lamp, is nearly as effective as an expensive apparatus. All cracks in the room should be stuffed up to prevent leakage.

THERAPEUTIC HINTS.

Impetigo in Children.—Until the crusts have fallen, G. Carrière employs gauze compresses saturated in a decoction of walnut leaves. He then applies peroxide-of-hydrogen compresses, covered with rubber tissue, renewed once a day. He also gives small doses of calomel internally.—*Le Nord Médical.*

Acute Serofibrinous Pleurisy.—For small effusions, C. E. Nammack (*Med. Rec.*, Mch. 9, 1901) applies guaiacol or iodine, gives magnesium sulphate, limits fluids ingested, and has patient take much table salt. He advises tapping if life is directly threatened or endangered by asphyxia from compression, or by cardiac weakness, or when the fluid has risen to the third front interspace, or in lesser effusions when spontaneous absorption is delayed for more than a few days. The underlying cause must also be treated.

Tympanites in Children.—Freyberger administers three times a day for two days a teaspoonful of

℞ Sod. sulphocarbol..0.25-0.50 (gr. iv-viii)
Syr. aurant cort.. 5.0 (ʒiʲ/₄)
Aq. menth. pip.... 25.0 (ʒviʲ/₄)

—*Jour. de méd. de Paris*, Feb. 17, 1901.

Stomach in Heart-Disease.—Carrière finds digitalis the most certain, but if there is flatulency he precedes a meal with ʒi of

℞ Tinct. nux vom....gm. 5.0 (ℳlxxv)
Tinct. gentian..... 10.0 (ʒiiss)
Tinct. rhei aromat.
Aq. lauro-cerasi aa. 20.0 (ʒv)
Aq. menth viridis ad. 100.0 (ʒiii-ʒiiss)

If the patient eats well have him take during the meal a tablespoonful of

℞ Ac. hydrochlor....gm. 3.0 (ℳxlv)
Strych. sulph. ... 0.5 (gr. ⅝)
Aquæ..... ..... 300.0 (ʒx)

or Coutaret's formula:

Ac. sulphuric....gm. 2.40 (ℳxxxvi)
Ac. nitric..... 0.80 (ℳxii)
Alcohol ..... 18.0 (ʒivss)

Allow to stand forty-eight hours and add:

Syrs. limonis....gm. 100.0 (ʒiii ʒiiss)
Aquæ ..... 150.0 (ʒv)

The food must be light, the patient quiet during digestion. For the attacks of gastric distress give a teaspoonful of

℞ Aq. chloroformi....gm. 60.0 (ʒii)
Cocainæ hydrochlor. 0.20 (gr. iii)
Aq. aurant flor.... 20.0 (ʒv)
Aquam ..... 40.0 (ʒx)

Uncontrollable vomiting may be relieved by adding to each feeding of milk one to four drops of

℞ Picrotoxin .....gm. 0.12 (gr. ii)
Alcohol, q. s. to dissolve
Morph hydrochlor. 0.06 (gr. i)
Atrop. sulph..... 0.01 (gr. ⅙)
Aq. lauro-cerasi.... 12.0 (ʒiii)

SATURDAY, MARCH 23, 1901.

SURGICAL PROPHYLAXIS OF NEPHRITIS.

We present in this issue of the Medical News a lengthy abstract of the address of Prof. Reginald Harrison (London) to the students of Cornell Medical College on Retrospects and Prospects in Genito-Urinary Surgery. One feature of the prospect in the surgery of the urinary tract Mr. Harrison touched on but lightly, perhaps because its initiation was due to his own labors. It is the question of the significance of kidney tension in the production of albuminuria and even of suppression of urine and the problem of operative relief for the condition.

Kidney diseases remain one of the therapeutic opprobria of scientific medicine. We have learned to diagnose the various forms of nephritis, but we are utterly unable to influence their course. Of late years we have come to realize more and more our helplessness in treating this class of patients, owing to the wear and tear of the strenuous life, and the greater addiction of men generally to spirituous liquors and irritating concentrated foods has become far more frequent than it was. It is universally conceded now that the acute nephritis, which frequently follows scarlet fever and other infectious diseases, not rarely is the starting-point of the chronic nephritis which so often proves fatal in adult life. Even with the most careful prophylaxis, however, these acute nephritides develop in certain patients. At times they run so insidious a course as to be unsuspected. In others they produce very marked symptoms.

Dr. Harrison proposes to interfere surgically in some of these severe cases. He considers that the effort to eliminate toxins present in the circulation leads to overcongestion of the kidney. The irritating nature of the toxic substances in solution in the blood provokes additional congestion by interfering with the vasomotor apparatus of the kidney. The delicate secreting material of the kidney is surrounded by an absolutely unyielding fibrous capsule. In addition to this there are partitions of fibrous tissue extending down to the hilum of the organ that prevent compensatory dilatation of congested portions. The result of this continued congestion is permanent injury of the secreting mechanism of the kidney. This state of overcongestion is not merely imaginary nor theoretical. After death from scarlatinal nephritis it is usual on autopsy to find the kidney intensely congested, the capsule tense and stretched, the whole organ of a shining dark color and overfilled with blood.

The clinical feature of these cases is the suppression of urine that leads to the fatal termination. Oliguria gradually progresses to absolute anuria and then so-called uremia develops. This urinary suppression Dr. Harrison attributes to what he calls renal glaucoma, that is, to a state of intrarenal pressure that inhibits function by interfering with the normal action and nutrition of delicate cellular tissues. The analogous condition in the eye from intra-ocular tension is well known, its sad results are now recognized and surgical measures for its relief are considered the only justifiable treatment. Mr. Harrison's suggestive name has been well chosen and he proposes to relieve the corresponding condition in the kidney by an incision that will relieve the intrarenal pressure.

He has had experience himself in several cases. In the first case it was expected that suppuration would be found in or around the kidney. The patient had had scarlet fever some three weeks before, and scanty albuminous urine with great lumbar pain were the permanent symptoms. When the kidney was opened a gush of blood relieved the pressure. The pain ceased at once. The urine gradually became more plentiful and the albumin disap-

peared. Until the improvement of symptoms took place it was thought that under mistaken diagnosis a needless operation had been done. Dr. Harrison has had some experience also in cases of persistent chronic congestion in which disorganization of the intricate secreting mechanism of the kidney was prevented by incision. Subsequent drainage prevented the recurrence of the congestion until the vasomotor mechanism of the kidney regained its control.

Dr. Harrison suggested in an article in the *Lancet* some time ago that "the operation should be reserved for cases in which there is evidence that the recuperative power of the kidneys suffering from nephritis is overweighted. When after an attack of this kind, the albumin is not disappearing from the urine and there is a prospect, unless some relief is found, of permanently damaged kidneys resulting, then a trial of this expedient (exploration through a small transverse lumbar incision with division of the kidney capsule where deemed advisable) may be undertaken without adding to the gravity of the circumstances." As these cases are absolutely unamenable to medical treatment and as even when an immediate fatal termination does not follow, subsequent chronic nephritis is not unusual. Dr. Harrison's suggestion may prove of great value in hitherto discouraging and almost hopeless conditions.

The subject is well worthy of the most careful study and would seem to justify surgical boldness that may lead to precious results in a field where present-day medicine feels itself almost more than anywhere else at a loss.

PHYSICIANS' ORPHANS' HOME.

No man gives so much gratuitous work to the world as the physician, and no man leaves so little behind him, for the reason that with his death his income stops abruptly. There is no business that can be conducted in his children's interest, no pension to be paid to his widow. And to make the outlook more hazardous it is a well-known fact that the physician's life is ten years shorter than the lawyer's, and fifteen years shorter than the minister's. Infectious diseases caught from his patients, pneumonias from midnight calls, and overwork reduce the average life of a doctor to forty-five years. For few indeed is there "slippered ease."

In order to increase his income he is generally obliged to live up to it, not being able to keep his home life apart from his profession, and the very spirit that makes him give all his time and energy to others precludes a selfish saving for himself. The consequence is that the accident of death often leaves a family of children, of fine intellectual heredity and good breeding with almost nothing for their support or education.

A Physicians' Orphans' Home for the children of deceased physicians appeals to us as a most wise and right object of charity. An organization has been effected to establish and maintain such a home for the care and education of the helpless little ones of brother physicians, by endowments and subscriptions from the profession, under whose management and control it will be.

The committee that has had the location for such a home in view has considered sites in Asheville, N. C., Louisville, Ky., Colorado Springs, Col., Canton, Ohio, and Lookout Mountain, Tenn., but has finally settled on Bristol, Tenn. and Va., as the place where the most suitable site may be obtained; and has secured an option on a certain hotel property, apparently well situated in wooded grounds. Thirty-five thousand dollars still remains to be raised in order to put the orphanage in operation; and to obtain this, as well as funds for its maintainance, a personal plea is being sent to every physician in the United States to assist the enterprise.

The object cannot fail to arouse the interest of every physician who is a father, if only out of pity for the child of his brother who may be left destitute. Not only physicians, but patients whom they may interest, will recognize that it is a movement of great economic value, as it will tend to develop some of the best material of a coming generation, and that it is a fitting tribute to the unselfishness of the profession.

MEDICINE, POETRY AND PROPHECY.

Mr. Stephen Philips is acknowledged to be the living English poet whose works deserve the most serious attention. No less than five important magazines have had articles on his work during the last month or two. The opening article in the January number of the English *Nineteenth Century and After* is a poem of prophecy by him reminiscent of the accomplishments of the century just past and glimpsing the work that the new one will do. It is interesting to note how much that the poet finds of real advance in the past is medical and how much of progress foretold must come from the profession whose un-

selfish work the public has, as a rule, misunderstood and at best is only just beginning to appreciate.

Speaking with the voice of the Lord in cadenced verse of striking dignity, the poet finds first to record the surcease from pain that Nineteenth Century medical progress has brought.

"In the years that have been I have made an oblivion for anguish,
And stillness in place of a cry.
I have lain around the knife as a numbness, on nerves as an ether.
I am He that hath healed, saith the Lord.
I have fallen as a veil upon woe, as a slumber on sorrow,
As a blank on the reeling brain.
In the years that have been I have shown me a smoother of pillows,
A closer of fixed eyes."

This is the main part of true achievement for man in the past. The future is radiant with progress that will still further lessen the weight of human suffering.

"In the years that shall be I will come as an healer to cities
And as dew to a parched land.
And the city of furnaces shall fade, the city of wheels,
The city of the white faces,
The girding city, the city of gongs, and of hammers,
Whose floor is of embers and ashes."

How tempting is the poet's vision of a city life that shall care first for the health of its people and thus for their true happiness! When the strenuous life shall be as if it were not, because its deep, wasteful, unwholesomeness shall be far from the common life of the people. Then the poet rises to the vision of further achievement when even the grave shall lose its victory and death its sting.

"And the dead whom ye loved ye shall walk with and speak with the lost
The delusion of death shall pass,
The delusion of wounded earth, the apparent withdrawal,
The snare of sightlessness vanish.
Ye shall shed your bodies and upward shall flutter to freedom.
For a moment consent to the ground."

So shall time bring mead of progress, thinks the poet, until pain and death are no more.

"At the wheels of my chariot pacing like alien captives,
Anguish and Time and Death."

The poet's ecstatic vision is too fair ever to be realized here below, but it is something for medical men to contemplate in the midst of sordid, unsatisfying realities that the highest ideals to which the poetic imagination can rise are intimately connected with the work of the profession to which they belong. It is provocative of a thrill of encouraging self-satisfaction at the beginning of the new century to realize that the daily round of little duties is a constant factor in the loftiest purpose there is—the lifting of humanity out of the pain and misery that have been its lot.

ECHOES AND NEWS.

NEW YORK.

Middleton Goldsmith Lecture.—This annual lecture under the auspices of the New York Pathological Society, will be delivered at the New York Academy of Medicine, No. 17 West Forty-third street, on Tuesday evening, March 26th, at 8.30 o'clock, by Prof. Charles Sedgwick Minot, M.D., Professor of Histology and Human Embryology, Harvard Medical School. Subject: "The Embryological Basis of Pathology." All members of the medical profession are invited to attend.

New York Academy of Medicine.—Section on Laryngology and Rhinology, Wednesday, March 27th, Dr. W. F. Chappell will present a paper on "Tuberculosis of the Tongue"; Dr. C. G. Coakley on "Tuberculosis of the Tonsils, Accompanying Tuberculous Glands of the Neck"; Dr. Emil Mayer will report on his "Clinical Experienced with Adrenalin."

The Section on Obstetrics and Gynecology will meet Thursday, March 28th. Dr. R. Waldo will read a paper on "Sactosalpinx Hemorrhagica" and Dr. A. F. Currier one on "Early Diagnosis of Ectopic Gestation."

Resignation of Dr. Delafield.—At the February meeting of the Board of Trustees of the School of Medicine of Columbia University the resignation of Dr. Francis Delafield as professor of the practice of medicine was accepted, to take effect June 30, 1901. Dr. Delafield had contemplated this step for some time. His connection with the school has been a long and close one. After his graduation in 1863 he was appointed clinical assistant to Dr. Alonzo Clark, the professor of pathology and clinical medicine; in 1882 he became Dr. Clark's successor. It is understood that Dr. Walter B. James, P. & S. 1883, will be his successor.

Health Board and Spitters.—The Board of Health is after the spitters in street cars, ferry boats and public buildings in earnest. At the regular meeting of the Board last week, a resolution was adopted directing the Sanitary Superintendent to enforce rigidly compliance with Section 194 of the Sanitary Code after April 1, 1901. The section referred to prohibits spitting in various public places. Members of the Sanitary Department would not say just what measures would be taken to enforce the law, but it was intimated that after the 1st of next month sanitary inspectors would ride about on

street cars and visit ferry houses and boats and public buildings and would arrest on the spot any person they caught spitting on the floor.

Sneak Thieves Abroad.—Dr. Clement Cleveland's residence was entered by sneak thieves who carried away some valuable jewelry.—In the lower West Side an ingenious sneak thief calls early with a note to the doctor asking him to call at a house in the vicinity. While the servant is taking the note to the, perhaps slumbering, physician, the thief "looks around." Later in the day the physician finds his note a blind and his prospective patient is not forthcoming; it may be that his overcoat has disappeared.

New York Medical Society for Clinical Research.—A society bearing this name has just been organized. Its object is to encourage young physicians to thorough clinical work and original research. To further these objects a library and laboratory have been established wherein the members may do their special work. The officers for the ensuing term are: Dr. Gutman, President; Dr. Mandel, Vice-President; Dr. Libman, Secretary; Dr. Spivac, Treasurer. Any regularly licensed practitioner who is a graduate of a regular medical college in good standing is eligible to membership.

Maternity Hospital Incorporated.—Daniel S. Lamont, Cornelius Vanderbilt, Frank L. Polk, Henry C. Thompson and William Thorne of New York, Moses Taylor of Mount Kensico and Percy R. Pyne of Barnardsville, N. J., are directors of the Manhattan Maternity Hospital and Dispensary of New York City, which filed articles of corporation March 18th with the State Board of Charities. It is proposed to maintain a maternity hospital and dispensary and a training school for nurses in New York City.

American Congress of Tuberculosis.—It is announced that the second annual meeting of the American Congress of Tuberculosis will be held at the Grand Central Palace, in the City of New York, on the 15th and 16th days of May, 1901. The medical profession of all countries is invited to contribute papers to be read before this Congress in their behalf by a committee selected for that purpose in case of the inability of the author to attend; and to enable those who could not hope or expect to be present to participate in the work and usefulness of the body. As the questions to be discussed involve remedial legislation, legislators, lawyers, judges, and all publicists, who take an interest in the subject, are also invited, both to enroll and contribute papers.

PHILADELPHIA

Hospitals Benefited by Charity Ball. The proceeds of the twenty-first annual Charity Ball were $11,200 which will be divided among the hospitals of the University of Pennsylvania, the Jefferson Maternity, the Philadelphia Orthopedic Hospital and the Infirmary for Nervous Diseases, and the Samaritan Hospital.

St. Joseph's Hospital.—The trustees of this hospital have recently appointed two pathologists, Drs. Randle C. Rosenberger and Alfred Hand, Jr., each of whom is to serve six months yearly.

Consumption a Notifiable Disease.—The Board of Health has taken the following action regarding consumption: *Resolved,* That tuberculosis be hereafter included in the list of pestilential or contagious diseases required to be reported to the health officer." Cases are not to be given publicity by the placarding of houses or by placing them under undue restrictions. It is the intention of the health authorities to coöperate with the medical fraternity in keeping consumptives under surveillance and thus check the spread of the disease.

Nurse Seeks Reinstatement.—A writ of alternative mandamus returnable March 25th has been secured by Miss Mariana Wood in her suit against the Pennsylvania Hospital for reinstatement to her position as nurse. Miss Wood was prominent in Philadelphia society circles, but entered the hospital as a nurse in 1898. In August, 1900, she was dismissed from the hospital for violating the rules by "slapping" a patient. Miss Wood has made fruitless efforts to appear before the managers of the institution to justify her conduct. It is now incumbent upon the hospital authorities to file a justification of Miss Wood's dismissal or reinstate her before March 25th.

Memorial Hospital in Pittsburg.—By the will of the late C. L. Magee nearly the entire estate of $6,000,000 is eventually to be applied to the founding of a general hospital to be known as the Elizabeth Steel Magee Hospital in honor of the testator's mother. The will, after stating that the hospital is to be open to the sick and injured of all classes, reads: "I especially desire the admission to this hospital of all females who may apply for admission thereto for lying-in purposes and that they be admitted without any questions being asked as to their past lives or names." A law passed at the last session of the Legislature prevents the building of the hospital on the grounds specified, as it prohibits the erection of a hospital in the built-up portions of the cities of the first and second classes. Memorials urging its repeal are being signed.

Whisky in Snake-bite.—Dr. Joseph McFarland at a recent meeting of the Pathological Society detailed the results of attempts to obtain immunizing serum from horses after the injection of snake-venom. Being asked by the President, Dr. Packard, if the effect of snake-venom upon the heart warranted the widely-spread the belief that whisky was an efficient antidote, Dr. McFarland replied that strychnine was more nearly a physiological antidote as death usually was due to paralysis of the re-

spiratory centers. He stated further that it was safe to say that whisky does more harm than good when given in cases of rattlesnake bite. Such bites are seldom fatal in this country under any treatment, the fatalities being probably less than 5 per cent.

Bubonic Plague Not Dreaded.—The Treasury Department on January 20th appointed a commission to investigate the alleged bubonic plague conditions at San Francisco, there being a controversy between the municipal authorities and the State officials on the point whether there was a genuine case of the plague in the city, the municipal authorities affirming the existence of it. As reported in the MEDICAL NEWS, the commission consisted of Prof. Simon Flexner, of the University of Pennsylvania; Prof. F. G. Novy, of Ann Arbor, and Prof. L. F. Barker, of the University of Chicago. Their report has been completed and submitted to Secretary Gage. According to a Philadelphia daily Prof. Flexner was asked to say something about the nature of the report. "I cannot, of course," he said, "make any definite statement as to the opinion of our committee, or even as to our work, until the proper authorities have published our report. There is, however, so marked, and perhaps so natural, a tendency in every community to worry over a thing of this sort that I am very glad to say that there is no occasion anywhere in the United States for any alarm." Prof. Flexner would offend against ethics, says the *Sun*, if he were to say that the bubonic plague had appeared in San Francisco. But supposing the existence of it to be proved there would be no cause for apprehension, judging from the success with which the medical men have combated the disease wherever it has been diagnosed. It has been proved that it thrives on dirt and bad ventilation, and quickly succumbs to prompt sanitary measures. In a squalid tenement district it would be dangerous only so long as the houses could not be cleaned and disinfected. The bubonic plague caused a scare when it first appeared in Glasgow, but its spread was soon checked and the deaths that occurred did not show a high mortality rate. There were familiar diseases prevalent at the same time which were more deadly. The plague was also reported at Manila, and there were fears for our army. They soon subsided, for the once dreaded fever overran no quarter. It is now officially existent in South Africa, but although the health of the British army is avowedly very bad, the medical staff is losing no sleep over the sporadic cases of bubonic plague. Historically its reputation could not be worse, but either it has lost its virulence or modern science is able to control it almost at will.

CHICAGO.

Bacilli in Books Harmless.—Health Commissioner Reynolds finds no necessity for disinfecting public library books, his opinion being based upon investigations made by Dr. Adolph Gehrmann, Director of the Municipal Laboratory. Cultures were taken from the books examined, which were selected by the librarian, and by Dr. Reynolds from the library shelves. In reporting the results, Dr. Reynolds says that no disease-producing bacteria were found on any of the volumes, only the ordinary bacteria usually to be found upon the human skin and upon everything handled by human hands.

Surgeons Must Report Deaths.—A bill introduced in the General Assembly of Illinois, March 7th, provides that it shall be the duty of every surgeon who performs a surgical operation, and of every physician who advises and arranges for the same, after which death results within thirty days, to report the same to the coroner of the county within twenty-four hours. It shall be the duty of the coroner to call a competent physician, who has had no previous connection with the case, to make a thorough investigation of all the circumstances before the coroner's jury and report the same as the statute provides in other cases. Violation of the provisions is made a misdemeanor punishable by a fine of $500 or thirty days' imprisonment.

Presumption of Miscarriage from Accident.—The Appellate Court of Illinois, First District, holds in Strehmann *vs.* the City of Chicago that the fact of a miscarriage within two months after an accident, coupled with the evidence of the woman's physician, that the accident, as described by her, might have caused the miscarriage, and no other cause having been proved, it would be a reasonable inference that the accident caused the miscarriage. Certainly, it says, it would be a question for the jury, on all the evidence, whether the accident was the efficient cause of the miscarriage. It holds that it was calculated to mislead the jury for the trial court by an instruction to single out one fact in evidence, namely, the birth of the still-born child, not stating other facts in evidence, and inform the jury that such fact considered alone did not tend to prove that the accident was the proximate cause of it.

Splenomegaly Primitive or Splenic Anemia.—At a meeting of the Chicago Pathological Society, held March 11th, Dr. Maximilian Herzog read a paper on this subject, which was based upon a study of the literature of the subject and upon two cases on which Dr. M. L. Harris had performed a splenectomy, both of which recovered. After the removal of the spleen, one of the cases in particular was studied carefully. Before the operation there had been present in this case a marked diminution of the erythrocytes, a low color-index, and an absolute and relative reduction in the number of the leucocytes. The blood had improved very much after splenectomy and there had developed a marked eosinophilia (14-11 per cent.). An examination of the spleens removed, weighing respectively 1,055 and 600 grams, showed a marked endothelial proliferation with enlargement of the blood lymph-spaces

(pulp-spaces). Herzog stated that he had sought in vain for many destroyed blood-corpuscles inside of lymph-endothelia, a picture as is, for instance, found in typhoid fever. Considering the fact that the blood condition had always improved in all cases of splenomegaly in which splenectomy had been performed, provided the patient did not die from the operation, it appeared conclusive that the changes in the spleen must be looked upon as the primary factor in the disease. From an examination of the two cases, as well as from a study of the literature, it appears that no evidence can be found that lymphatic endothelia destroy the blood by directly taking up blood-corpuscles. Herzog therefore advances the theory that lymphatic endothelia of the spleen and of lymph-glands secrete an erythrolytic ferment and in this manner destroy old and worthless blood-corpuscles. In splenomegaly there is an enormous endothelial proliferation, and probably in consequence a largely-increased production of the erythrolytic ferment, which, when present in such a large amount, destroys many healthy blood-corpuscles. If the spleen is removed, the source of the increased production of the erythrolytic enzyme is removed, and the blood improves rapidly and permanently.

A Case of Vesico-Sigmoidostomy.—Dr. E. J. Senn, at the Chicago Medical Society, March 13th, presented a very interesting case of exstrophy of the bladder in a young man, twenty years of age, upon whom he performed a vesico-sigmoidostomy. At the same meeting, Dr. E. W. Andrews showed a specimen obtained from a Bottini operation which was performed by him about a year ago. He has done the Bottini operation sixteen times, with one death. Dr. F. Kreissl exhibited a suprapubic drainage-tube of his own design. He claimed that by using this tube drainage of the bladder through the suprapubic fistula is so thorough that leakage of the urine alongside of the tube is almost completely obviated. He showed a specimen from the genito-urinary tract in a case of tetanus following the removal of a tumor by the suprapubic route. He also showed a specimen obtained from the genito-urinary tract after a Bottini operation.

Dr. Daniel N. Eisendrath presented an interesting case of inoculation tuberculosis from cattle-hide with multiple foci on the arm. He also reported a case of renal and vesical calculus with treatment of post-operative anuria, and detailed the history of an instructive case of perforation of the cecum with pericecal abscess.

Gangrene of the Appendix Simulating Infection following Labor.—Dr. Denslow Lewis reported the case of an English woman, thirty years of age, the mother of two children, aged three and five years respectively. She was delivered, after a normal labor, of her third child. After narrating the case in detail, he spoke of the relationship of appendicitis to different gynecological conditions. Twenty-three times he has noted an agglutination of the appendix, normal or diseased, to a right pyosalpinx or ovarian abscess. In a large pelvic abscess which he operated in 1888 by abdominal incision and counter-drainage by the vagina, the attending physicians as well as himself were surprised to find a relationship to the appendix which resulted in a fecal fistula that finally healed. Reported cases seem to sustain the assertion that invasion may be from the appendix to tube or ovary or from the uterine adnexa to the appendix. These possibilities are understood and looked for and the various sequelæ have been described. He has had no experience with appendicitis during labor and the case reported is his first occurring early in the puerperium. It is not unlikely that appendicitis often exists at these times and is usually overlooked. Pregnancy, the puerperium and even the early stages of labor, far from constituting a contra-indication for operative interference, show an additional danger from which the patient can only be safeguarded by a prompt operation.

GENERAL.

Southern Notes.—Atlanta, Ga., opened a new Hospital for Incurables, on March 2d. It has ten beds and is under the supervision of Dr. J. M. Brawner.—The Woman's Medical College of Baltimore celebrated the twentieth anniversary of its founding February 22d.—The Memphis Hospital and Medical College, Memphis, Tenn., will be started next week and it is hoped that it will be ready for occupancy next November.—Dr. F. E. Daniel has become editor of the *Texas Medical Journal, vice* Dr. S. E. Hudson, resigned.—Kentucky State Medical Society will hold its forty-sixth annual session in Louisville, May 22, 23, 24, 1901; Chairman, Dr. L. Frank, Louisville.—Louisiana State Medical Society holds its next annual meeting at Tulasne Medical College buildings, April 18, 19, 20, 1901; Secretary, Dr. A. G. Friedrichs.

Cocaine Legislation.—The Tennessee Legislature passed a bill last month prohibiting the sale or presentation of cocaine save on a physician's prescription, and providing for a penalty of from $100 to $500 upon conviction of violation. A similar measure, though extended to the sale of morphine, opium, and chloral, is before the Legislature of Missouri. A similar measure in Georgia was killed through ignorance of its purpose on the part of a few legislators. The fate of a like Alabama measure is unknown. It was reported some time ago that the city ordinance in Knoxville, Tenn., restricting the sale of cocaine to physicians' prescriptions, has been partially defeated by the action of certain physicians in selling prescriptions to habitués; and it was declared that some step would be taken to remedy this.

Smallpox in United States.—Ohio had the largest number of smallpox cases last year, 1,666; Tennessee coming next with 1,303, and Minnesota third with 875.

Royal Red Cross for Nurse.—The Royal Red Cross, which King Edward VII. has just conferred upon Mme. de Ferrières, Superintendent of the French Hospital at Johannesburg, was instituted in 1883 as a recognition of services rendered by women in connection with the nursing of the sick and wounded of the British army and navy. Among the first upon whom it was bestowed was Miss Nightingale. Countess Roberts is also entitled to wear it. The cross is a handsome ornament, being of crimson enamel, edged with gold, and bearing on the arms the words "Faith, Hope, Charity," and in the center Queen Victoria's effigy. Queen Alexandra is, of course, a member of the order.

Congress against Alcoholism.—The State Department is informed that an international congress against alcoholism will be held in Vienna from the 9th to the 14th of April next. The United States Government is invited to send delegates. The program includes discussions upon the effects of alcohol; diseases, heredity, degeneration, and criminality caused by its use; and means to combat alcoholism, both of legal and private initiative. Partizans of the moderate use of liquors, as well as the adherents of total abstinence, are admitted to the congress.

Medical Students in Berlin.—At the University of Berlin this winter there were 1,312 students of medicine.

American Laryngological Society.—The Council has decided that the seventh annual meeting of the American Laryngological, Rhinological and Otological Society shall be held at the New York Academy of Medicine in the City of New York May 30, 31, and June 1, 1901.

Gift to New Montclair Hospital.—Joseph Van Vleck, a wealthy citizen of Montclair, has offered to give $8,000 toward the erection of a new hospital, provided the Board of Governors raises $42,000.

Pennsylvania and the Cocaine and Morphine Evils.—The demand from lay interests which has been made in Pennsylvania during recent years that pharmacists be prevented from selling narcotics to habitués has resulted in the following clause in a bill which has been introduced in the Legislature: "No person shall sell or furnish morphine, or its salts; cocaine, or its salts; opium, or any preparation containing 10 per cent. or more thereof; or chloral hydrate, to any person known to be addicted to the habitual use of any of these articles as a narcotic, nor to any person when written notice has been given to the proprietor or manager of the store or pharmacy that such person is addicted to the habitual use of any such articles as narcotics."

In commenting on this bill the *Chicago Bulletin of Pharmacy* says: We deem this an admirable solution of the cocaine and morphine evils—so far, that is, as the law may furnish correction. As we said last month, 'even with such a law the pharmacist should not forget that considerable responsibility yet remained to him, and that his duty would be plain to save the unfortunates from themselves so far as he found it possible so to do.' But to discuss the question of a legal remedy alone, such a provision as the one under consideration seems to us much better calculated to control the evil than any which has been previously suggested or applied. The plan adopted in most of the southern cities and States, where the evil has been particularly vicious and rampant, and where the question of a remedy has become one of vital importance, is that of prohibiting the sale of narcotics save upon a physician's prescription. But this has not been found to succeed well in practice. As a recent correspondent has said, 'since there is no law to prevent the refilling of prescriptions, one prescription may be made to do service for the whole community.' Moreover, there are physicians in every large city who, for a consideration, are willing to give prescriptions *ad libitum*, in which case the pharmacist, whether inclined to check the evil or not, has no recourse but to fill the order. The Pennsylvania method furnishes within itself a self-acting agency. The enforcement of the law prohibiting the sale of narcotics is largely given to any member of the victim's family. A wife, mother, or son who desires to prevent a habitué from securing that which not only ruins his own life, but largely the lives also of those who are dependent upon him, has the means of protection at hand."

St. Louis Medical Society of Missouri.—At its last regular meeting, March 16th, the following papers were read: "Our Present Knowledge of Hydrophobia," by Dr. Carl Fish; "Recent Modification of Pasteur Treatment," by Dr. John C. Morfitt.

Adirondack Cottage Sanitarium.—The last annual report by the Medical Director of this excellent charity, Dr. E. L. Trudeau, is encouraging for the friends of this institution. The running expenses for the year have been fully met by the contributions and permanent increase has been made to the buildings and the various funds, notably the Endowment Fund which has had about $20,000 added to it this year. The sum of $130,000 is wanted in order to make a fund, the interest of which will adequately provide the running expenses. The medical report is promising. There were 262 patients treated, 170 being new patients; of these 55 were apparently cured, in 79 the disease was arrested, 25 were improved and 11 were unimproved, and one died. Since 1884, when the Sanitarium was founded, the histories of as many patients as possible have been followed. Of the 1,176 patients discharged during the fifteen years, one-half were living, one-half of these being perfectly well.

Obituary.—Dr. Paul von Seydiwitz, a surgeon, scientist and newspaper man, died in

New Orleans on Friday, March 15th. He was a native of Schleswig-Holstein, where he was born in 1821 of a distinguished family. He graduated from the University of Heidelberg, but left Germany in 1848, being involved in the revolution of that year, and moved to Paris. He remained at Paris ten years. He spent some time in Russia, where he pursued his medical studies. From Paris he moved to London, where he was a fellow of the Royal College of Surgeons. After many wanderings he went to New Orleans in 1884 and had lived there ever since, corresponding for various European papers, writing on scientific topics and practising his profession. He was appointed expert on infectious and contagious diseases by the Louisiana Board of Health, represented the United States Marine Hospital Service in the Jacksonville yellow-fever epidemic of 1888 and was also sent to Venezuela and Central American to investigate epidemic. During the late Spanish-American War he served as assistant surgeon on several occasions.

Dr. Henry Mitchell Smith, of New York, died of pneumonia last week at Escondido, Cal., where he had been visiting. Dr. Smith was born in this city in 1835. He was a member of the American Institute of Homœopathy and Secretary and Treasurer of the Hahnemann Monument Fund.

Dr. John Sargent, the oldest physician in Jefferson County, N. Y., is dead at Woodville, aged eighty-seven years.

Dr. James W. H. Lovejoy, aged seventy-six years, died at his home in Washington, March 19th. Dr. Lovejoy was chairman of the executive committee of the Children's Hospital, and also served several terms as president of the Medical Society of the District. He was one of the incorporators of Garfield Hospital, and had been president of the faculty of the Georgetown University Medical School as well as professor of practice of medicine.

Old Dominion Hospital.—This hospital, connected with the Medical College of Virginia, at Richmond, is about to be enlarged so as to accommodate forty more patients.

University College of Medicine Hospital.—This building, adjoining the Virginia Hospital, Richmond, is nearly completed. It will have a capacity of some sixty or more patients. Its clinical amphitheater is built on the most approved plans, having all the convenient arrangements for demonstrations, etc.

Tri-State Medical Association of the Carolinas and Virginia.—The third annual session of this body was held in one of the halls of the Jefferson Hotel, February 26 and 27, 1901, and was a marked success in every respect. The President, Dr. Charles W. Kollock, of Charleston, S. C., presided with ability, and Dr. J. N. Upshur, Richmond, Secretary, was untiring in his duties.

In his address, the President, Dr. Kolloch, favored the abolition of the delivery of a formal President's Address, as the time could be put to more valuable use. He thought that a high standard of educational requirement should be required of both teacher and pupil, and that particular attention should be paid to the ethical instruction received by the pupil, while the standard is maintained by the teacher. The methods used in the selection of college faculties are often lax—very frequently the selection becoming more or less of a family affair. When a vacancy occurs, it should be widely advertised, and the candidates be made to undergo a most thorough test. Then men less pretentious, though more meritorious, could be secured—men whose fault is lack of pull.

The fourth annual session will be held in 1902, at Asheville, N. C. Hereafter there will be a Chairman in each of the three States, for the Sections on Medicine, Surgery, Gynecology and Obstetrics.

The following officers were unanimously elected for the incoming term: President, Dr. John N. Upshur, Richmond, Va.; Vice-Presidents, Drs. J. W. Long, Salisbury, N. C.; S. C. Baker, Sumter, S. C.; Hugh M. Taylor, Richmond, Va.; Secretary and Treasurer, Dr. H. A. Royster, Raleigh, N. C. To fill vacancies in the Executive Committee: South Carolina—Drs. W. P. Timbermann, of Timbermann, S. C., three years, and Manning Simons, Charleston, one year; North Carolina—Dr. J. W. Marsh, Fayette, two years; Virginia—Drs. Southgate Leigh, Norfolk, two years, and J. S. Wellford, Richmond, three years. Dr. J. C. Hemmeter, Baltimore, was elected Honorary Member. Subject Selected for Special Discussion during Session of February, 1902, Tuberculosis—Dr. J. A. Burroughs, Asheville, N. C., Leader.

CORRESPONDENCE.

The Giving of Commissions and Division of Fees.

To the Editor of the Medical News:

Dear Sir: In the Medical News of February 9th I was much interested in a discussion by members of the Chicago Medical Society relative to the "Giving of Commissions and Division of Fees."

I should like to get my finger in your buttonhole and burden you with my views on the subject. The line of work I endeavor to follow obliges frequent consideration of the subject under discussion and, being personally acquainted with four members of the Committee of Five to whom the resolutions were referred, kindles in me a spirit to say a word in defense of the surgeon and at the same time something in behalf of the general practitioner. In the first place, no conscientious physician, be he surgeon or general practitioner, desires in any way to lessen the dignity of the profession.

That being the case the question of com-

missions at once disappears and leaves only for consideration the one important subject of "Division of Fees." "The laborer is worthy of his hire." If the surgeon's work is such as demands unusual skill and an extended knowledge of pathology and technic, acquired only after years of seemingly endless work, expense, sacrifice and self-denial then his remuneration should be in proportion to the value of his service and the financial ability of his patient. Every surgeon who performs a major operation, be it from three seconds to three hours in duration, takes upon his shoulders the responsibility of a human life or at least an individual's future welfare and happiness.

These cannot be reckoned in dollars and cents.

When a client consults his attorney relative to the preservation of a piece of property the title of which is rightfully vested in him, but which, owing to a legal technicality, is liable to be swallowed up by some big corporation, the first question the lawyer asks is: "What is the value of this property?"

On being told it is worth from four thousand to five thousand dollars the lawyer, if he is "up to date," agrees to undertake the work and go "halves." Now this unfortunate client well knows that he is "up against it," but keeps a stiff upper lip and agrees to the proposition. The same man if he were asked two thousand or twenty-five hundred dollars to save his boy in an attack of appendicitis would, in all probability, roar even louder than the editor of the *Chicago Times-Herald* in commenting on the size of a surgical fee for work, the gravity and importance of which he apparently has not the conception of an idea.

And it is ever thus. The man who poses as the great disseminator of truth to the benighted layman will invariably expose the dwarfed proportions of his microscopic soul by burdening the world with his exalted opinion on a subject he is as unqualified to discuss as the veriest ragamuffin that runs the street.

The vast majority of such editors compliment the talented attorneys on the enormous fees they command and never lose an opportunity to "lambaste" and bemean a reputable, conscientious physician.

I have operated on something over one hundred cases of appendicitis and, although that is a small number compared with what surgeons in large cities encounter, I feel at liberty to speak to the point on the subject.

It is but fair that the family practitioner should receive full compensation for his services in proportion to the rôle he fills. If he assists in the operation and bears half the responsibility, he should receive one-half the fee. If he makes the diagnosis and outlines the course of procedure, but assumes no responsibility in the operation, he should be remunerated accordingly and whatever amount he receives (I advocate a liberal one) should be paid him by the patient as it has nothing whatever to do with the special fee for the operation.

This is with equal justice to patient, family practitioner and surgeon, and should not unbalance or disturb the harmony and mutual friendship existing among them. In conducting my work such has been my practice and so far it has proven satisfactory to all concerned.

If a physician treats a family for twenty years and does not receive twenty-five hundred dollars he has, in all probability, not been called upon to tender very much service, or else his service has not been of much value and he is conscientious enough to charge accordingly.

The fact that he has, or has not, realized a good yearly income from a certain family cuts no figure in determining the amount of a surgical fee for operation on one of its members.

ORVILLE O. WITHERBEE.

612 Frost Building, Los Angles, Cal., February 24, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, March 9, 1901.

THE LOSSES FROM SICKNESS OF ARMY IN SOUTH AFRICA—THE LIVERPOOL SCHOOL OF TROPICAL MEDICINE—DEATH OF DR. MYERS OF THE YELLOW FEVER EXPEDITION TO BRAZIL—A CHAIR OF TROPICAL MEDICINE TO BE FOUNDED TO HIS MEMORY IN UNIVERSITY COLLEGE, LIVERPOOL—SANITARY RULES FOR THE PREVENTION OF MALARIA—CONTAGION AS A FACTOR IN PROPAGATING TUBERCULOSIS—SMALLPOX IN GLASGOW—THE DISEASE CARRIED TO EDINBURGH—SANITARY PRECAUTIONS IN SCOTLAND—ELABORATE PRECAUTIONS IN LONDON AGAINST AN OUTBREAK OF PLAGUE.

A VERY interesting article on the losses in the South African War through sickness has been published in the *Daily News* by a statistician who has made a careful study of the official figures. It appears that the army of occupation probably never exceeded 220,000 men and that at present it is a dwindling force (shortly to be reinforced) of about 200,000 men. For the four weeks ending April 28th the deaths from disease show a weekly average of 188. In a force of 200,000 this represents a death-rate of .094 per cent. or of nearly 49 per 1,000 per annum. During May and June the death-rate rose to 71 and 63 per 1,000 respectively. For the three months 3,007 men out of 200,000 died of disease, yielding an annual death-rate of 60 per 1,000. The death-rate of the Army at home is between 4 and 5 per 1,000. Turning to the last six months of the war, the figures, if less acute, are hardly less disquieting seeing that no crisis occurred. During the half year ending January 31st last 2,816 men have died of disease giving a rate of 28 per 1,000 per annum. In India, with a climate obnoxious to Europeans, the death-rate of the British troops is little

more than half this figure. The last four months show an increasing death-rate, thus October, 22 per 1,000; November and December, 27; January, 36. The losses of the army from sickness which lead to the invaliding home of the men is much greater than those from death. In April, May, and June the loss through sickness was 3,000 deaths and 12,000 invalids, or a loss of strength at the rate of 300 per 1,000 per annum. In the five months, April to August, there were 4,000 deaths from sickness and 30,000 men were invalided home; in other words, the Army was losing at the rate of 70,000 men on a basis of 200,000. Turning to the last six months 2,816 men have died of disease and 13,090 have been invalided home—a total loss at the rate of 159 per 1,000 per annum.

An influential meeting has been held at the Town Hall in connection with the Liverpool School of Tropical Medicine "to consider the subject of health and sanitation in West Africa and the Tropics in the light of the researches of the three malaria expeditions of the School of Medicine. On several occasions in my letters I have referred to these expeditions which the extraordinary enterprise this only recently-established school has organized. The Chairman, Mr. A. L. Jones, referred in feeling terms to the death of Dr. Walton Myers, who with Dr. Durham volunteered to go almost without remuneration on the expedition to Brazil. Both contracted yellow fever after making a necropsy in a case of the disease. Dr. Myers succumbed. He was only twenty-eight and had taken high honors and gave great promise. Owing to the action of the shipowners and others a Chair of Tropical Medicine will be endowed in University College to be called the Walter Myers Chair. Sir William Church, President of the Royal College of Physicians, said that when he was present two years ago at the inaugural meeting of the School he was surprised at the enthusiasm with which the movement was taken up, alike by members of the medical profession and by leading commercial men in Liverpool, Manchester and other centers. Referring to malarious countries, he said it had been computed that the mere machinery of government cost more than double the ordinary amount—in other words it took two men to the work of one. If the mortality could be reduced one-half the volume of trade might be greatly increased. Many of the malarious countries were the richest on the globe. Therefore money spent in investigating their disease was beneficial both from a commercial and a humanitarian standpoint. Major Ross of mosquito fame described briefly the results of the expeditions. As to sanitary matters he said that the best water-supply was rain water. All other sources were contaminated by the natives. But during the dry season water-supply was a difficult question and well, spring and river water had to be used. As to European houses, those of Government officials were generally well situated, but those of the various trading companies were generally placed in bad positions—in low-lying districts close to swamps and the crowded huts of natives. After a visit of eight months, covering a large extent of Nigeria, the members of the expedition arrived at the following conclusions as to how malaria might be prevented: (1) Living apart from the natives at a distance of about half a mile. Native children to a surprising extent harbor the malarial parasite in their blood, and it is conveyed thence to Europeans living close by. European quarters are almost invariably surrounded by native huts; the nearer the quarters are the more unhealthy is the district. On the other hand, quarters situated at a distance from native huts are very healthy. (2) Surface drainage of the areas around European quarters. This measure without the previous one would not be efficient; combined with it the two together would ensure complete freedom from malaria in Europeans. He hoped some day to see tracts of West Africa reduced by careful sanitary regulation to the comparative condition of salubrity at present enjoyed by a tropical country which was once as unhealthy as the unhealthiest—India.

To the Feburary number of the *Polyclinic* the editor, Mr. Jonathan Hutchinson, has contributed an important article on Tuberculosis Problems. The doctrine of contagion is, he thinks, carried too far. He suspects that the bacilli are almost ubiquitous and possibly exist in a latent state in almost every individual. The fact that no local epidemics of phthisis are ever observed is opposed to the idea that contagion plays an important part, as is also the fact that no races or communities are known in which, irrespective of habits and occupations, the disease is rife. In a general way it may be said that the decadence of tuberculosis is in proportion to the prosperity of the nation. During the last half century England has witnessed a remarkable decline, and this although no special measures have been taken to prevent contagion. We have been prosperous, and meat, fat-foods, bread, milk, beer, and wine have been cheap. The repeal of the Corn Laws was the best means of legislation which could have been contrived for the diminution of consumption. The hastily-assumed association between intestinal tuberculosis in children and raw milk has been shown to be mistaken. Calves even when fed from tubeculous udders scarcely ever contract the disease.

Although the sanitary authorities of Glasgow profess to have got a grip on the smallpox outbreak, 19 fresh cases were reported yesterday and three deaths, making the death-roll 120 while the cases in hospital number 387. Thirty patients have been dischaged from

hospital cured. A case of smallpox was discovered in one of the common lodging-houses in Edinburgh. The patient was a man who with another had tramped from Glasgow. A number of persons in contact with him have been put in quarantine. The Glasgow outbreak has caused great sanitary activity in Scotland, for that city has intimate relations with the rest of Scotland. Hospital accommodation is being provided and vaccination and revaccination are being offered free. In places near Glasgow, such as Paisley, special activity is shown. Lists of persons living in Glasgow and employed at Paisley have been prepared, so that they may be kept under observation.

The London County Council are taking elaborate precautions in view of the possibility of plague visiting London. Their Public Health Committee is authorized to expend, if necessary, a sum not exceeding $250,000 for precautionary measures. The following provisions are recommended as necessary: (1) Accommodation ready at the moment when required; (2) accommodation which can be got ready in a few hours; (3) accommodation which can be got ready in a few weeks. For the first separate quarters for "suspects" and "contacts" are being prepared in each of the four divisions of London to accommodate 212 persons. For the second purpose accommodation with be provided for another 200 persons, which will involve the immediate acquisition of additional premises at an estimated cost of $80,000. For the third purpose a scheme has been prepared for temporary buildings for 600 persons to be erected on land in the Council's possession at a cost of $90,000. These buildings will not be erected unless plague actually appears in London, but provisional contracts will be made and all necessary arrangements completed, so that in case of emergency the work can be begun without delay.

TRANSACTIONS OF FOREIGN SOCIETIES.

APPENDICULAR HEMATEMESIS—FREQUENCY AND CAUSE OF CERTAIN APPENDICAL SYMPTOMS—HYDROCELE—MENINGITIS SECONDARY TO INFLUENZA—TYPHOID CONTAGION.

Dieulafoy, at the Academie de Médecine, February 12, 1901, discussed hematemesis as a complication of appendicitis. He stated that it is not an extraordinary symptom, because he has himself noted six cases within one year and several writers have mentioned it in literature. The hematemesis is habitually preceded by true bilious vomiting, afflicts children as well as adults, recurs at rather short intervals, and usually ends in death. The quantity of blood ejected varies from 200 or 300 to 800 c.c., is usually fluid and red, but may be clotted and blackish. Patients who have been operated on too late are those who are attacked in this way. This complication is only the expression of a general toxemia and of the virulent infectious character of the disease, which is proved by the fact that these symptoms occur along with others of septicemia, as albuminuria, urobilinuria, moderate or severe jaundice, etc. The effect of this toxemia upon the gastric mucosa is the cause of the bleeding. Postmortem examination has showed small ulcers, situated chiefly at or near the pylorus, occurring singly or multiple. The conclusions are that appendicitis is a toxo-infectious disease which threatens the entire economy and the cure of which is dependent directly upon the time at which the operation is done. The earlier the better in all cases. Lucas-Championnière in discussing this condition at the meeting of February 19th, said that hematemesis after appendicitis operations is comparable to black vomit which so often appears after other severe laparotomies. While the gravity of the appendical hematemesis is admitted he differs in holding that it is curable, as has within his experience several times occurred with the aid of gastric lavage with alkaline fluids. The report of Dieulafoy tended to show the frequency of severe attacks of appendicitis and the essential gravity of this disease in itself, which seems at the present time to be increasing. If these conditions had existed in the past, it is difficult to see how their observation and record could have so entirely escaped so many competent practitioners. A parallel is offered by the fact that appendicitis has lately been reported as often complicating pregnancy. Pinard has recently seen it three times within one month, while the speaker during a past ten-year experience in midwifery did not find it once. He therefore holds that if appendicitis is not strictly a new disease it certainly differs materially from the typhlitis and perityphlitis of our forefathers. As supporting this view he quoted his own statistics. From 1882 to 1899 he opened thirty-four large right iliac fossa abscesses of appendical origin, of such nature and degree that only rapid incision, evacuation and drainage could be done. From 1899 to 1900 he had treated in the same manner nineteen parallel cases. If appendicitis were not augmenting in severity and since so many preventive operations are done, we should expect a vast decrease in the number of such abscess cases. If the same ratio had been maintained through the first-named period the total would have been one hundred and fifty-two cases. The later great augmentation seems to show an increased virulence, and probably depends upon the increasing causes of all intestinal infections. Setting aside those cases of appendicitis which seem to depend upon influenza, as was recently demonstrated by Faisans, the speaker pointed out the remarkable frequency of appendicitis among the meat-consuming nations as illustrated by the United States and Great Britain. In his own private practice most of his patients have been meat-eaters, inordinately or almost exclusively. In addition to this error in diet is the disfavor with which free catharsis is regarded.

Periodic judicious use of purgatives will no doubt act as a preventive measure, but not as a curative measure. The really curative treatment of appendicitis is strictly surgical.

Robin, in the discussion said that he has noticed the frequency of appendicitis among patients who have suffered more or less from gastric or intestinal dyspepsia, or both. The most common type he considers to be gastric hyperasthenia. As to the nefarious effects of certain forms of diet, he considers animal food as harmful and has found as high as twelve per cent. of nitrogenous matter in the feces of meat-eaters upon careful chemical analysis. He likewise considers carefully dietetics and the regulation of the bowels as very important. Lancereaux stated that he had recently cured a woman of appendicitis by purges, repeated in full doses on each of three successive days.

Peyrot, at the meeting of February 5th, read in the name of Milian and himself notes as to the pathogenesis of chronic hydrocele, teaching that it exists as a consequence of alterations in the tunica vaginalis, independent of any epididymo-orchitic lesions. In this sense a chronic hydrocele is perivisceritis, precisely as is the case in pericarditis, pleurisy and peritonitis, with which it is very often found in association. The cause of such chronic hydrocele should be upon the same basis as that of these other ordinary perivisceritis. As in them, tuberculosis is not by any means to be considered the ruling etiological factor. Cardiopathies, nephrities, arteriosclerosis and such systemic disorders are rather the true causes or the associated conditions, beneath which in common lie general systemic infections, benign or malign, which may leave behind them some local chronic inflammation.

Rendu, at the Société Médicale des Hopitaux, February 1, 1901, communicated a case of cerebrospinal meningitis secondary to the grip. The child had for a few days complained of a nasopharyngitis and later was overtaken by pain and paresis of the lower extremities and absence of the patellar reflexes, Kernig's sign, stiffness of the neck, etc. These symptoms improved shortly under warm baths several times daily and the withdrawal by lumbar puncture of about twenty-five cubic centimeters of spinal fluid. The pains in the lower extremities and stiffness of the neck soon vanished, but the muscular weaknesses persisted. The explanation of this seems to be that the cerebral element probably disappeared altogether, while lesions of the cord gray-matter either lingered or were permanent, or the anterior nerve-roots were affected. Cultures from the cerebrospinal fluid persistently remained sterile

Trosier claimed that true contagion is not at the bottom of every case of enteric fever developing within the hospitals. For example he cited a woman in his own service who was attacked by the disease thirty hours after admission. In this instance it is likely that the disease was inoculated upon her by water, filtered but not boiled, used in lavage which was her treatment at the time.

Vincent in the discussion held that except by contagion there is no explanation for the spread of the disease among the nurses and attendants assigned to care for typhoid patients in such institutions and military prisons. The sequence of the infection seems to be, first, the hands, then the food, and, finally, the system. If the water were at fault, attendants elsewhere in the hospital would also be affected.

SOCIETY PROCEEDINGS.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held February 11, 1901.

The President, Dr. L. Hektoen, in the Chair.

Osseous Stylo-hyoid arch.—Dr. Thomas R. Crowder described three cases. The stylo-hyoid arch is a constant structure in the higher vertebrates. In many, as the horse, cow and sheep, it is completely bony; in man it is largely ligamentous. Developmental defects with more or less ossification are not infrequently found, but complete bony arch is rare. The three cases presented were not recognized before death. The anomaly is to be looked upon as a developmental defect, and not as an ossification of the stylo-hyoid ligament once developed in the normal way. It has no clinical significance beyond the possibility of fracture—an unlikely accident.

Blastomycetic Dermatitis.—Dr. F. G. Harris reported a case of blastomycetic dermatitis in a woman seventy-eight years old. The growth was located on the gluteal region and commenced four years ago as a pimple, which became a roughened area of intense itching and later became apparently denuded. The growth was 11 centimeters long by about 6 centimeters wide, having an elevated border bearing flattened papillomatous outgrowths which overhung the floor, the latter being covered with villous-like epithelial projections interspersed with areas of ulceration. The entire growth was movable on the underlying tissues; there were no secondary growths on any part of the body, nor were there any evidences of syphilitic infection. Microscopic examination showed a hyperplasia of the *rete mucosum* which grew down into the corium in branching, coral-like projections. In these epithelial downgrowths were miliary abscesses containing the blastomycetic organisms which were present in groups of three or more. Many of them were in the process of budding. There were no cultures made from this case on account of the diagnosis not having been made clinically.

In the discussion of Dr. Harris' paper Dr. Lieberthal referred to a case recently observed, in which a provisional diagnosis of syphilis

was made, where the blastomyces were found in sections. He still held to his original diagnosis.

H. T. Rickets said that the histology of blastomycetic dermatitis is a specific one and entirely different from that of tuberculosis and syphilis.

H. G. Anthony spoke of the points of difference between blastomycetic dermatitis and the syphilitic and tubercular lesions resembling it.

L. Loeb called attention to the fact that blastomycetic dermatitis had not been produced experimentally.

W. E. Coates compared blastomycetic dermatitis to certain diseases in plants. He considers the organisms observed in the skin lesions as spores of fungi.

F. G. Harris stated that his case was treated with iodides for three weeks without any improvement.

Carcinoma of Lungs.—Dr. Le Count demonstrated a diffuse secondary carcinoma confined to the lymph-channels of both lungs of a man who died from carcinoma of the stomach while in the service of Dr. Kramps at the St. Elizabeth Hospital; the condition was correctly diagnosed during life. At the necropsy, the usual large metastatic tumor nodules were found in the liver together with an extensive involvement of the peripancreatic, retroperitoneal, peribronchial and peritracheal lymph-glands; the adrenals were the seat of a very extensive carcinomatous growth; there were small tumors in the outer parts of both kidneys. The primary tumor from which all these metastatic growths arose was located near the pylorus and showed no features other than are often observed in gastric carcinomata. The lungs were alike in appearance; both possessed very extensive subpleural, linear, branching and tortuous carcinomatous growths in the lymph-channels as well as tumor masses in the lymph-channels of the deeper parts of the lungs. There were no nodular growths in the lungs, as are observed in consequence of the embolism of tumor-cells. The lungs were fresh, no microscopic examination having been made, but the gross appearance supported in all its details, the opinion that a retrograde lymphatic metastasis had occurred in these channels from the lymph-glands at the roots of the lungs.

Toxic Action of Formaldehyd.—Martin H. Fischer reported the results obtained from a study of the toxic effects of formaldehyd and its aqueous solution, formalin. The inhalation of formaldehyd is accompanied by marked inflammatory changes throughout the respiratory system. Dyspnea, depression of temperature, tachycardia, weak pulse, and vomiting follow the introduction of formalin into the stomach. Sudden death may result. The severity of the symptoms and the degree of histologic disturbance bear no relation to the strength or quantity of the injected formalin. The gastritis is characterized by intense congestion, necrosis and leucocytic infiltration. Intraperitoneal injections produce a fibrinohemorrhagic peritonitis of varying intensity according to the strength of the solution. The peritonitis following chronic formalin-poisoning produced by injecting small amounts of dilute formalin intraperitoneally is accompanied by great connective-tissue proliferation and a striking eosinophilia. Subcutaneous formalin injections produce marked exudation and leucocytic infiltration. The introduction of formalin into the conjunctival sac is followed by an iritis, which when a single drop of the concentrated chemical is used may be sufficient to permanently injure the eye.

In whatever way formalin is introduced into the body, certain systemic changes result. Degenerative changes and focal necroses are found in the liver and kidneys. The leucocytic infiltration following the introduction of formalin is characterized by the eosinophiles appearing first; these are followed by the other polynuclears; last of all appear the mononuclears. It is believed that differences in osmotic pressure are to be held accountable for the exudation. The death of the cell is accounted for in two ways, (1) by disturbances in osmotic pressure and (2) by a deleterious chemical action—probably the reducing power of formaldehyd.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held February 25, 1901.

The President, George B. Fowler, M.D., in the Chair.

Dangers of Syphilis.—Dr. Prince A. Morrow read a paper on the medical aspects of the social evil. He said that syphilis is worse than any foreign pest, although so much care is taken and so much money is spent on sanitary precautions to prevent the entrance of these diseases, while syphilis is allowed to go absolutely unguarded. It has been calculated that one-eighth of all the patients in hospitals are suffering from venereal disease or its consequences. We have no data on this question here in New York, because, unfortunately, they are considered shameful diseases, whose admission would, as the lawyers say, "degrade or incriminate" a patient and so the actual condition of the affairs with regard to their prevalence remains unknown. Syphilis is rather an urban, than a rural disease.

Prevalence of Gonorrhea.—With regard to gonorrhea its prevalence is well known. Neisser, the discoverer of the gonococcus, says that it is the most universally prevalent of contagious diseases with the single exception of measles. In cities in Europe where statistics are available it is said that more than one-half

the population, or even in some cases more than three-fourths of the male population have, or have had, gonorrhea. With regard to syphilis, Fournier states that 15 to 23 per cent. of the patients under treatment in the general hospitals of Paris are suffering from syphilis or some of its sequelæ. As the hospitals are recruited from the various classes of the population of the city, he concludes that about one-seventh of the population of Paris is syphilitic. These figures probably apply to New York with equal force. Of dispensary patients about ten per cent. of the patients in an ordinary hospital are treated in the genito-urinary dispensary. Besides these a number of venereal cases are treated in the skin clinics, a number more in the gynecological clinics, and no insignificant number in the eye, ear, throat and nose clinics.

Army Venereal Statistics.—Cunningham stated some time ago that in British India, as the result of investigations made in 1885, it was found that 53.7 per cent. of invalided soldiers suffered from venereal diseases. About 30 per cent. of these suffered from syphilis. During one year there were over a million days of service lost as the result of venereal disease. Twenty-five per cent. of the soldiers who returned from India to England were syphilitic. It is to be hoped that our soldiers who come back from the Philippines will not bring the disease back with them in any such proportion as this. It may be stated that the British army statistics show a higher proportion of soldiers suffering from venereal disease than that of any other army. The reason is the neglect of precautions in the matter, because of the objection of the Anglo-Saxon mind has to acknowledging the danger of the social evil for the army.

Seriousness of Gonorrhea.—While formerly gonorrhea was thought to be a simple disease, it is now known to be very serious. The gonococcus has been found capable of affecting all the serous membranes. It readily attacks the inner or outer linings of the heart, or even the peritoneum. A large number of fatal complications have been reported of late years as the result of these gonococcic invasions. It is generally conceded that most salpingitis is gonorrheal and that many of the diseases of the uterus and the adnexa have the same etiology. Some of the Germans go so far as to say that 80 per cent. of gynecological affections are due to the gonococcus. Most of the children who lose their sight shortly after birth do so because of gonorrheal ophthalmia. This disease still continues to furnish a large contingent to blind asylums, and 10 to 20 per cent. of all the blind owe their affliction to gonorrheal infection. Formerly the number of such cases was even larger, running as high as 40 to 60 per cent. At the present moment there are in Germany, according to Neisser, 30,000 patients who are blind because of the gonococcus. Neisser is sure that many are saved by the Credé method and believes that this should be even more widely practised than it is at present. Gonorrhea has more to do with failure of the population to increase than has syphilis. At least 20 per cent. of sterile marriages are due to gonorrheal processes either in the husband or wife and 90 per cent. of the cases of azoospermia that occur owe their origin to gonorrheal affections of the epididymis.

Frequency of Syphilis.—Syphilis affects the general population much more than is thought. It has perhaps not increased in recent years, but its presence has been more insistently urged upon the medical man's attention, because he has learned that many affections, formerly thought to be unconnected with it, are really complications of the disease. Only a quarter of a century ago the main symptoms of syphilis that attracted attention were its cutaneous accidents. Now these are looked upon as entirely subsidiary. The important lesions of the disease are those that occur in the internal organs. Nervous, renal, hepatic, intestinal syphilis and syphilis of the bones—these are the affections that now rivet one's attention. In the first rank of tertiary symptoms of syphilis come undoubtedly the lesions of the brain and cord. Parasyphilitic diseases as they have been called, that is, affections of the nervous system apparently not directly connected with syphilis and yet occurring practically only in individuals who have had syphilis, have attracted a great deal of interest in recent years.

Syphilis Insontium.—It has been thought that the acquirement of syphilis meant guilt, but the feature of the disease is that it occurs with unfortunate frequency among those who are absolutely innocent. Often these patients are without the benefit of prompt treatment, because husbands from whom the disease is contracted are fearful that their victims should find out the real nature of the malady. Of 100 cases of syphilis in women in the St. Louis Hospital, Paris, Fournier found in 19 that the disease was due to conjugal infection. At St. Louis the proportion of questionable characters that come for treatment is larger than at most hospitals. Seventy per cent. of syphilis in women under treatment at the New York Hospital is due to conjugal infection. The disease spreads very easily in a household. Nurses contaminate children, children sometimes infect nurses. Mothers infect nursing children, the little ones are fondled by other members of the household and thus syphilis becomes spread throughout the family.

Syphilis and Medical Practitioners.—Surgeons and accoucheurs, genito-urinary specialists and even general practitioners are much more often the victim of innocent syphilis than is usually known. Dr. Morrow has seen more than fifty cases in medical men in which syphilis was innocently contracted while in the pursuit of their profession.

Hereditary Syphilis.—Syphilis is the disease which is most transmitted by heredity. While the hereditary character of most other diseases

has been limited, hereditary syphilis has become even more significant. Sixty to 80 per cent. of stillborn children owe their premature death to syphilis. Most of the children born during the active stage of syphilis in the parents suffer very severely from the ravages of the disease which they inherit. Rickets is almost exclusively syphilitic in its origin.

Significance of Venereal Diseases.—It is evident then that venereal diseases are of immense social significance, yet no attempt is made to limit their spread. In many cases it is evident that venereal disease owes its spread to almost wilful negligence; at times apparently deliberate malice. At the present moment the extermination of contagious disease is the watchword of the sanitarians. Why, then, should venereal diseases be ignored? Not a single city in this country has regulations for the prevention of the spread of venereal disease. Is it that such regulations are beyond the sphere of municipal authorities? Syphilis is twenty times more contagious than tuberculosis and almost as severe in its ravages. A sad feature of venereal contagion is that it is mostly the young and immature who are affected by it—women of eighteen to twenty, men of twenty to twenty-five. Their lives are practically ruined by a thoughtless act under the stress of temptation at the moment when they are most in need of protection.

Prostitution as a Cause.—There is no doubt that prostitution is the *fons et origo* of venereal diseases. Can prostitution be suppressed? It is a Utopian idea to think that prostitution can be exterminated. It has existed in all ages; it is not an indispensable evil, but it is an inevitable one. Our present laws take a certain amount of cognizance of it. They send the brothel-keeper to prison. They punish street solicitation, but they go no farther. Our laws acknowledge the existence of the evil, but do not attempt to regulate it. Legal regulation of prostitution exists in France, Germany, and Austro-Hungary. It has been recently reëstablished in Italy, and, in a certain limited way, it existed in England and Norway for over twenty years, between 1860 and 1890. The method of regulation adopted is by the registration of prostitutes who are legally required to be examined by a medical man at regular intervals and who are confined in the hospital whenever they suffer from a contagious disease. This is evidently an attempt to hygienize an insalubrious occupation. The principle on which the regulation is founded would seem to be the same as that which forbids the selling of bad wares. The trouble, of course, with any system of regulation is that clandestine prostitution continues and unless most stringent measures are instituted, the number of unexamined prostitutes becomes larger than those who are under the law. In Paris, for instance, the number of legally-constituted houses of prostitution has come down from 250 to less than 40 during the last twenty-five years. In Marseilles the number has become reduced from 120 to 19; In Bordeaux, from 60 to 18. The amount of clandestine prostitution has increased in at least the ration that legalized vice has decreased.

Increased Danger.—Where legal regulation of prostitution exists, but is not properly enforced, the danger of the spread of venereal disease becomes greater. The vice that flaunts itself in music- and dance-halls is less under control and more dangerous than open prostitution. One difficulty with all present methods of regulation is that only one element in the spread of venereal disease, the female, is brought under the influence of the law. The man also should be submitted to medical examination. Another difficulty with the law is in its application. When the police have discretionary power this readily becomes a means of blackmail and persecution. The serious objection to legal regulation of prostitution is that it proves a provocation to vice. It removes one of the deterrent features by lessening the fear of disease. The hygienist and the moralist should work together. So far they have seemed to be working at cross-purposes.

Vice Crusades.—The spasmodic attacks of virtue in a community that lead to harsh measures against the vicious classes often do more harm than good. The efforts of the reform administration in this city five or six years ago simply drove vice from its usual haunts and scattered it broadcast throughout the city. The volume of vice was not diminished; it was only diverted from its usual channels. True reform must not come simply from effort at repression, but from consideration of the different phases of the question and an endeavor to provide remedies for many concomitant evils. Homes for fallen women must be founded and encouraged in order to give these people a chance to rise from their present condition. The age of consent in women must be raised by law so that the present recruits to the ranks of prostitution, as the result of early seduction of young girls, shall cease. The purveyors of vice who tempt young women into taking up a life of prostitution must be punished severely and must be hunted down without compunction. Dance-halls must be suppressed when of bad character, or thoroughly regulated when it does not seem that their only object is the encouragement of vice, or the providing of a place of assignation. Even with all this entire reformation will not come. Regulation of the evil that is left will be necessary. Public opinion in this country will not permit the licensing of vice, as it is called. The French system was tried at St. Louis in 1872, but it lasted for but one year and then was swept away by the combined efforts of all the religious people of the State.

Hospitals and Venereal Disease.—Nothing could very well be more important for the prevention of the spread of disease than the provision of hospital accommodation for those affected by venereal disease so that they may remain in the hospital until such time as their disease is no longer contagious. Our accommodations, however, in the hospitals of large cities

for the treatment of such patients is miserably inadequate. There is not room in the hospitals of New York for one in 2,000 of the prostitutes who are known to be in the city. Altogether there are just 26 beds in which syphilitic women can be treated. These are in the City Hospital, for no other hospital in the city will receive such patients. As the result of this discouraging state of affairs, because of false notions of delicacy and morality, not one in ten of those affected by syphilis are properly treated. Provision for the treatment of syphilitic men is scarcely better. There are 56 beds for the treatment of male patients in the venereal wards of the City Hospital. In addition to this there are a few in the Metropolitan Hospital. The plea that syphilis is refused because of its contagiousness is only a pretext. Any hospital can provide against the possible contagiousness of the disease and that without very much trouble.

Venereal Wards.—Every hospital in the city should provide free beds for the treatment of venereal patients. This would do more to supress the source of the contagion than any other possible measure that can be applied at the present time. Patients suffering from venereal diseases are reasonably anxious to be well treated, but often have neither the time nor the money. In the night class at the New York hospital which is opened for surgical cases, but which receives venereal diseases, 70 per cent. of the patients received for treatment are suffering from venereal diseases. Dispensaries should be established in quarters of the city where patients can easily reach them and they should be opened at hours when patients do not have to lose their work in order to attend them.

Avoidance of Infection.—All possible sources of infection should be eliminated as far as possible. Chancres should be excised. Mucous patches in the mouth should be cauterized, acid nitrate being the best remedy to employ. Patients should be instructed as to the possibilities of their spreading contagion. Often when the cutaneous lesions disappear, patients think themselves cured. It is impossible fully to instruct patients in these matters and a printed slip of instructions should be handed to each patient. These slips should contain information as to the necessity for syphilitic patients not to use towels and sponges that are liable to be used by others and should tell them of the danger of spreading the diseases through table articles, pipes, or anything that has been in their mouths. The danger of conveying their disease by inheritance should also be set before them.

Medical Knowledge.—In order properly to combat the further spread of venereal disease medical men should have more knowledge on this subject. The profession must take its stand before the world as the exponent of moral as well as physical health. It must be well understood that medical men are decidedly of the opinion that continence is not incompatible with health, that harlotry is no substitute for marriage, and that self-restraint and personal purity are very valuable measures for the preservation of health.

Statistics Worthless.—Dr. Frederic Sturgis said in discussing the paper that this subject has already been thrashed out many times. Medical men have often said that restriction of prostitution and regulation of the evil are needed, and we have all said "Amen, amen." Nothing, however, has come of the discussion and this one will probably have as little effect as any of the others. It is claimed that venereal diseases produce much more fatality than they did years ago, but there are those who doubt this claim. Of late insurance companies have been taking more care in the acceptance of life insurance on individuals who have had venereal disease and there has been serious question of putting such risks into a class of sub-standard lives. It is probable, however, that alcoholism has a great deal to do with the fatality supposed to be due to venereal disease. The alcoholic factor is more important than the venereal one. Fallen women seem to suffer very little in health from the ravages of venereal disease. It is a well-known tradition among them that if they leave "the bottle" alone they have good health. Owing to the neglect of the alcoholic factor all present statistics as to the fatality of venereal diseases are worthless.

Duration of Syphilitic Contagion.—It is important to know how long syphilis is contagious. It is probable that after the first twelve months of the disease its contagiousness practically disappears. This is a rule, however, which admits of many exceptions. In any given case no assurance can be given, until a longer period than twelve months has elapsed. There is no doubt at all that if a prophylaxis for smallpox exists there should be one also for greatpox. Surveillance is possible. There have been other experiences in this country other than that at St. Louis with the legal regulation of prostitutes. Nashville and Louisville also enforced such measures for a while and with some success. Public opinion was so much opposed to it, however, that the medical examination became a farce, the medical visitor merely asking whether all were well and then being invited to sit down to a bottle of wine. The system of regulation worked very well in St. Louis for a while. Women of the streets became themselves the enforcers of the law for those who attempted to avoid its burdens. It might seem a surprising thing to find that New York should have such poor accommodation for syphilitic patients, but there are so many disgraces attached to New York hospitals that this is not surprising to those who know something of the conditions.

Increase of Syphilis.—Dr. Charles Warenne Allen said in discussion that several years ago he suggested, as one of the best measures for lessening the social evil and avoiding its

physical dangers, the giving of more publicity to the present knowledge of venereal disease. There seems no reason to doubt that here in New York syphilis is on the increase. Dr. Allen gives figures from the Good Samaritan Genito-Urinary Dispensary. In 1887, 27,000 patients were treated, of whom 327 suffered from venereal diseases; in 1888, 38,000, 635 venereal; in 1889, 62,000, 2,000 venereal; in 1890, 73,000, 2,300 venereal; in 1895, 90,000, 2,700 venereal; in 1900, 86,000 and over 3,000 venereal. The speaker reported a case in which family infection had taken place from a nurse. The nurse conveyed the disease to the child, the child to the mother, the mother to other children and finally to the father. Five cases of syphilis resulted from the introduction of a syphilitic nurse into the family. It is eminently desirable that in a hospital, patients, and especially women patients, should be retained until they have passed their contagious stage. One difficulty with the present condition of affairs as regards syphilis is the objection to the word itself. The disease could be talked about much more freely, and precious information with regard to it conveyed, if it were to be called by some other name. Dr. Allen suggested some years ago the use of the word lues. The important thing for the prevention of the spread of venereal disease is the wide dissemination of knowledge with regard to the subject.

Failure of Medical Agreement.—Mr. William H. Baldwin, Jr., Chairman of the Committee of Fifteen, for the Suppression of Vice in New York City, was then asked to take part in the discussion. He said that he had come to be instructed and not to teach. It is evident after this evening's discussion that medical men are not agreed among themselves as to the significance and importance of venereal diseases. There is among the general public a great desire for knowledge on these subjects, because it is hoped to improve present physical conditions. Every one, including such as may not themselves be strictly moral, is desirous of bettering the present ethical condition. This cannot be done, however, unless there is an agreement as to the proper means to be adopted for this purpose. The International Conference on Venereal Diseases at Brussels a year ago agreed that regulation of prostitution was ineffective and inexpedient. There it was decided that what was best was a spread of knowledge on these subjects among the people. Doctors must enlighten the general public on subjects that are now deliberately kept in obscurity. This must be done in a healthy-minded way. At present when vice is driven from its favorite haunts by ill-advised restrictive measures, it betakes itself to the hitherto morally-clean parts of the city. The tenement-houses particularly are apt to suffer and the influence of bad example in crowded quarters is intolerably depraving. Vice is flaunted in the face of the young and children learn the mysteries of immorality from their earliest years. This must not be allowed. Vice tends to particular localities. Let it be kept there. A prominent minister of the gospel said not long ago that to confine these people to a particular locality was to make a little hell on earth, which would be better than to have a big hell throughout the whole city.

Vice Regulation at Present.—Mr. James B. Reynolds, the head worker of the University Settlement, said that his experience for the last two years in New York has been in the heart of the "red light district." It has been said in this discussion that the public opinion of English-speaking people will not permit police regulation of prostitution! In New York, however, there is at the present moment more regulation of prostitutes than there is in Paris. The tax imposed on fallen women is heavier than it is in Paris and it is better collected. It is a fiction to suppose that these women are not known to the police. If the public has tolerated this, why will it not tolerate better directed legal regulation? For better, for worse, we are launched on reform and we must go on. It has also been said this evening that nothing can be done and that the present discussion will prove as futile as have so many others. The heritage which the Twentieth Century has received from the Nineteenth, however, is this: all things, even human action, come under the name of Science. Sociology and its development in a practical way will give us the remedy. Already light is being thrown on a great many subjects in the relation of man to man that were supposed to be beyond the range or the help of Science. The difficult question of the social evil will be solved as have the others.

BOOK REVIEWS.

Uterine Tumors, Their Pathology and Treatment. By W. Roger Williams, Fellow of the Royal College of Surgeons, London. William Wood & Company, New York, 1901.

Those who know Dr. Roger Williams' book on cancer of the uterus will be sure to expect an interesting, practical and thoroughly scientific book on the subject of uterine tumors. They will not be disappointed. Dr. Williams in the Preface states that, in his opinion, the true task for medical authors of the Twentieth Century must be the generalization and reduction to order of the vast masses of chaotic facts which constitute medical law. To this end nothing will be more conducive than the writing of reliable monographs. The author has fulfilled very well this expressed purpose.

Information of the most varied kind, treating of all branches of the subject of tumors, will be

found. The chapter on very large tumors contains a list of the largest neoplasms removed. The record tumor is a cystic myoma removed by Severanu of Bucharest, which weighed 195 pounds. The abdominal distention in the case was enormous, measuring six feet at the level of the umbilicus. The question of the origin of malignant from myomatous tumors forms a very interesting discussion of a much-vexed problem. Among the assertions made are these: According to Bayle, 20 per cent. of all women over thirty-five are affected by myomatous tumors. Dr. Williams thinks there can be no doubt as to the reality of the fact observed by many, yet doubted by good authorities, that cancerous disease may primarily originate in a myoma. It is a rare occurrence, only about a dozen instances of it have been recorded, but it does undoubtedly happen.

The chapter on Lymph-gland Dissemination contains the latest and most interesting scientific work on this important practical question. It involves, of course, the question of the recurrence of cancer and the whole subject is well treated. In general the subject of cancer of the uterus is very up to date. So much has been written on the subject that much of the material here presented comes with an air of familiarity, but the condensation has been very well done.

The Medical Diseases of Infancy and Childhood. By Dawson Williams, M.D. Second edition, revised with additions by Frank Spooner Churchill, M.D. Lea Brothers & Co., Philadelphia and New York. 1900.

This work is a decided advance on Dr. Williams' first edition, admirable as was that little book. In this second edition the author has been fortunate in having Dr. Churchill as his American collaborator, and no small part of the up-to-date character of the work is due to the American editor. It has been the aim of the author to give pictures of the various diseases which shall emphasize the differences from their manifestations in the adult, so that the book is just what it professes to be—a treatise on disease in infants and children.

The subject of infant feeding is so large that it is of necessity inadequately treated; but the chapter on food will prove of great value to those young practitioners who are not familiar with the methods of home modification of milk, nor with the principles that guide one in percentage feeding. The illustrative cases are very instructive, and in this particular the book has followed the admirable plan of Rotch's able presentation of the subject. The reviewer thinks, however, that it would be better to advise putting babies to be weaned on formulæ much lower in proteids when first taken from the breast. The change to stronger formulæ should then be made just as rapidly as the absence of vomiting and of curds in the stools will permit. This for the reason that maternal milk, which analyses 4.0 fat, 7.0 sugar, and 1.5 proteids, is about twice as easily digested as the laboratory milk of exactly the same chemical strength. Moreover, in home modification the use of the Materna apparatus is liable to result in the food being given too sweet, for the accurate measurement of the milk sugar in so large a vessel is difficult or impossible.

The author is to be complimented on the clear presentation of the important subjects of summer diarrhea and intestinal toxemia. The technic of lavage, of colon irrigation, and of all the best methods of treatment, is given in full, so that a comprehension of this chapter by every practitioner would result in the saving of thousands of lives every summer.

In the chapter on bronchitis and pneumonia the physical signs are admirably described, and the differences from the signs in adults clearly noted. In the treatment the author makes no mention of the usefulness in bronchitis and bronchopneumonia of the mustard jacket nor of inhalations of vapor from the croup-kettle; instead, graduated baths, warm or cold, are strongly advised.

Other chapters especially good are those on tuberculosis, rheumatism, hydatids, rickets and adenoids. In the last, however, no mention is made of the persistent and distressing spasmodic cough which is at times the only symptom of nasopharyngeal vegetations. Bromoform is recommended in whooping-cough, notwithstanding the well-known danger of the drug when given in emulsion, and despite its uncertainty of action. One misses the articles on achondroplasia and Mongolian idiocy in the former edition, but the full discussion of cretinism makes up for this loss. In the chapter are several reproductions of the illustrations in Osler's valuable article on sporadic cretinism. A good colored plate illustrates Koplik's spots which are so useful in the early and differential diagnosis of measles.

The author's long experience in the East London Hospital for Children makes the book one which every general practitioner would do well to have at hand. Throughout the work the best methods of clinical diagnosis are accurately described, and numerous references to journal articles and monographs add much to its value as a hand-book of the medical diseases of children.

Urinary Diagnosis and Treatment. By John W. Wainwright, M.D. G. P. Engelhard & Company, Chicago. 1900.

Dr. Wainwright's little book is one of the series of monographs issued by the Engelhard Publishing Company. It is a very practical little manual and will undoubtedly prove of excellent service to the student and the practitioner. The series of plates giving the appearance and color of crystals that are found in the urinary sediment is an excellent feature and very well executed. Some of the proof-reading has not been very carefully done. The practitioner who, following the instructions of the book, buys a half-inch instead of a one-twelfth-inch lens in order to examine urine bacteriologically will not bless the individual to whose carelessness the error is due.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, MARCH 30, 1901. NO. 13.

SPECIAL ARTICLE.

REPORT OF THE COMMITTEE OF THE MEDICAL BOARD OF BELLEVUE HOSPITAL, APPOINTED JANUARY 2, 1901, TO INVESTIGATE AND REPORT UPON QUESTIONS RELATING TO THE GENERAL ADMINISTRATION OF THE HOSPITAL.

ON January 2d, last, you directed your Committee of Inspection and the President of the Board of Managers of the Mills Training School to report, at as early a date as possible, such suggestions as would tend to the better administration of the Hospital. In accordance with these instructions, we beg leave to submit the following:

The Reception Office.—The Reception Office is utterly inadequate to the demands made upon it. At present, there are from 200 to 300 applicants for admission daily, and from 60 to 100 of these are admitted to this Hospital; the remainder are sent to other Hospitals of the Department or are referred to the Dispensary for treatment.

The space provided was at one time adequate for this work, but the great increase, which the above figures show, taxes the accommodation far in excess of its capacity. The positions of the rooms are such that they are badly ventilated and poorly lighted, and the construction is such that both sexes must be accommodated in the same general admission room, so that here the sober, the intoxicated, the very sick and even those who are fatally injured must be received. At one end of this room partitions are erected, which, however, are not arranged so as to secure privacy, nor maintain for the examining physician the quiet essential to the proper performance of his duties.

We would suggest that more commodious, better lighted and ventilated quarters be found for this work, and that provision be made to secure the order and quiet which is necessary for the examination of patients before they can be properly assigned.

We would also suggest that the physicians, who are engaged in receiving, examining and distributing patients at the Reception Office, be relieved from all clerical duty, as this is a detail which can be performed by a clerk and which, if lifted from the admitting physician, would give him more time for his exacting and important duty.

Granting that the above suggestions are adopted, the fact still remains that the large number of cases which have to be disposed of compels the expenditures of such an amount of time on the part of the House Staff of Physicians and Surgeons that it interferes seriously with their duties elsewhere. We would suggest, therefore, that an arrangement be made by which they may be relieved from this duty and that it be placed upon a staff especially appointed to this work, the details of the arrangement to be determined after conference with the Commissioner.

Number of Cases Admitted to the Hospital in 1900.—In connection with this question it is interesting to note that 24,300 patients were admitted to Bellevue Hospital during the year 1900, and that 11,370 of these were ambulance cases. Many of these 11,370 cases were in such an enfeebled state, either from disease or injury, that they required special care and attention in the Reception Office, but owing to the conditions above mentioned, it was difficult, and in some cases impossible to give it there.

Number of Ambulance Cases for the Same Period.—Of these 11,370 patients, the ambulances belonging to Bellevue brought in 4,616, of whom 128 were so ill that they died within twenty-four hours after admission. The other hospitals in the city delivered 6,754 patients in their ambulances to Bellevue, representing transfers from their own wards or cases of a kind they do not admit to their wards; of these, 107 died within the first twenty-four hours of admission. The following table shows in detail the numbers received from the ambulances of these several hospitals, together with the deaths within twenty-four hours which occurred among these admissions.

PATIENTS RECEIVED FROM OTHER HOSPITALS.

Hospital.	Admitted.	Deaths.
Harlem Hospital	287	4
Gouverneur Hospital	1,956	20
St. Vincent's Hospital	618	16
New York Hospital	473	4
Hudson Street Hospital	711	4
Presbyterian Hospital	772	11
Roosevelt Hospital	1,549	41
Flower Hospital	283	6
J. Hood Wright Hospital	59	1
German Hospital	19	0
Fordham Hospital	2	0
St. Luke's Hospital	12	0
Columbia Hospital	13	0
Total	6,754	107

The large number of ambulance cases delivered to us by other hospitals materially affects our death-rate, but we cannot escape this burden so long as they are authorized by law to impose it upon us. We append a comparative statement of the death-rate in this and other hospitals of this City.

MORTALITY REPORT.

Year.	Hospital.	Number of Patients.	Died.	Per cent.
1900	St. Luke's Hospital	2,370	338	14.21
1899	German Hospital	3,091		5.48
1900	Presbyterian Hospital	3,322	394	11.82
1899	Roosevelt Hospital	2,013	326	10.50
1900	Mt. Sinai Hospital	3,270		10.19
1900	New York Hospital	6,032	329	5.44
1900	Pennsylvania Hospital	4,079	394	10.12
1900	Massachusetts General Hospital	4,816	407	8.45
1900	Boston City Hospital	7,945	939	11.81
1900	Bellevue Hospital	24,300	1,722	7.08

Selecting from the above list the hospitals situated in New York City,[1] it is seen that, combined, they provide for a total of about 21,098 patients annually, with an average mortality of 9.44 per cent.; whereas this Hospital provides for about 24,300 patients annually with a mortality of 7.08 per cent.

Recording Office.—We would also ask attention to the inadequacy of the accommodations to be found at the office set aside for keeping the records of administration of the Hospital. It is open to the same criticism that we bestow upon the other office; that is, it is badly lighted, poorly ventilated, crowded and noisy. The importance of these two bureaus in the conduct of any hospital is such that we trust they will not be lost sight of in the improvements contemplated.

Insane Pavilion.—Continuing our report, we consider next the Insane Pavilion. The medical service rendered here is of a mixed character. Questions of insanity are dealt with exclusively by two physicians who are paid by the City and are outside the jurisdiction of this Board; all other medical questions are under the control of this Board.

As has been stated elsewhere in this report, the House Staff, in addition to their duties in the general wards of the Hospital and Reception Office, are also responsible for the care of the patients in the Alcoholic Pavilion, the Emergency Hospital, the Erysipelas Pavilion, the Tuberculosis Pavilion, and the Prison Wards. During the past nine months they have also been required to assume charge of the insane, a service which calls for special knowledge and experience such as the members of the House Staff cannot be expected to possess.

We, therefore, renew the recommendation made to you nine months ago by the Committee of Inspection, that the patients sent to the Pavilion for the Insane be placed under the charge of a competent, well-qualified physician, with suitable salary, who shall devote his time exclusively to their care. There should also be an Assistant Resident Physician so that the Pavilion may never be without the presence of a competent medical attendant. The Resident Physician should be held absolutely responsible for the condition of every patient.

Nursing Service in the Insane Pavilion.

	Number of Patients	Died.	Per cent.
[1] City Hospitals	9,032	910	9.28
Metropolitan	4,542	381	8.43

The nursing service of the male ward of the Pavilion should be in the charge of a carefully selected, supervising graduate nurse, assisted by trained asylum attendants. In the opinion of the Committee, male pupil nurses are not fitted for the care of the insane. In this connection we refer you to the accompanying report of the President of the Board of Managers of the Mills Training School upon the conditions which have prevailed in that Institution.

Touching the nursing done in the female ward, it appears to have been as good as circumstances required—the result, no doubt, of the presence of a supervising graduate nurse, the system approximating in some degree that recommended for the male ward.

Alcoholic Wards.—Wards 32 and 34 of this Hospital are set aside for the reception and care of patients who, though not insane, are apt to be noisy and irresponsible, and who cannot be properly guarded in the general wards of the Hospital. Most of such cases are alcoholics, but some few are the victims of nervous disorders, such as certain forms of epilepsy and hysteria, in which phases of temporary mania may develop. These wards are the only places offered as a free refuge to patients of these several classes, coming from Manhattan Island and the Bronx. When it was opened the number of patients annually treated therein was about 3,000, the numbers now vary between 5,000 and 6,000 each year, nearly one-fourth the entire admission to the Hospital for the corresponding period. The space was adequate for the three thousand yearly admissions, but with the large increase it is often severely congested, so that not infrequently patients must sleep on mattresses placed on springs on the floor, the number of ordinary beds not being sufficient. This does no special harm and does not serve as an unbearable discomfort, but such crowding is not sanitary and not advisable, and would not be permitted if adequate accommodations were available.

The increase in the number of alcoholics is due to several causes: (1) The increase in population, which, however, is the least. (2) To the fact that, as always, most of the alcoholics of other hospitals are sent to Bellevue. (3) To the large number of cases of acute drunkenness which are brought in by their friends or by the police to sleep off their condition here rather than sleep it off at home or at the station house. (4) To the increased number of alcoholics who, finding themselves well cared for, come in again and again to be treated—go out and return. These repeaters vary in their attendance from two to three times a year to, as in one instance, forty times within nine months. This clearly is an imposition, but it is very difficult when a man is in a state of intoxication to determine promptly whether it is the only diseased state

which he presents, or whether some very serious condition may not be hidden beneath. It is, therefore, hazardous to refuse admission to cases of acute alcoholism. But in the opinion of the Committee, relief from this congestion may be obtained by securing a transfer to the workhouse of those who can be classed as habitual drunkards, as is shown by the following attempt to put this in practice.

In the six weeks beginning May 15th to July 1st past there were 462 male alcoholics and 161 female alcoholics; of these there were 60 males who were repeaters. A recommendation was therefore made by the Committee of Inspection to the Commissioner to the effect that a competent person be delegated to visit these wards daily, take out those who were repeaters, bring them before a magistrate and have them committed to the workhouse as habitual drunkards. This did not seem, in the opinion of the Commissioner, wise at that time. In order to test the efficacy of this plan in reducing the number of these repeaters, the Visiting Physician in attendance tried the method of threatening the above action to those who should come a second time. This was tried only in the male wards. The result was that during the following six weeks, from July 1st to August 15th, the number of admissions fell from 462 to 381 and the repeaters from 60 to 12. The admissions in the female ward were 181. Since that time, however, finding that this threat was not carried into effect, the number of admissions each month has gradually risen until during the six weeks from November 15, 1900, to January 1, 1901, it has gone up to 532 in the male wards alone.

Cases of Epilepsy, Etc.—Another cause of overcrowding in Wards 32 and 34 is the fact that they are the only places in the Hospital in which certain forms of epilepsy, hysteria and even surgical mania can be cared for. They cannot be treated in the general wards because they are not only disturbers of the peace but are sometimes dangerous to other patients or to themselves, requiring a degree of confinement and special care which cannot be secured there. Caring for such cases in wards to which alcoholics are assigned is an evil, but for the present it cannot be avoided in this institution, for the simple reason that there is no other place in which they can be provided for.

The Committee recommends that the members of the Visiting Staff exercise closer supervision of these wards than heretofore, and also suggests that the House Physician and Senior be assigned to the duty of these wards, rather than Junior, as has been the case in one instance, as the latter's experience has hardly been sufficient to entrust him with such responsibilities as must face one in these wards.

We refer to the report made by the Managers of the Mills Training School for particulars concerning the nursing in these male wards. In the female ward, as in the Insane Wards, it appears to have been as good as circumstances permitted.

Other Wards of the Hospital.—The general wards of the main Hospital Building are clean, and, considering the style of architecture, comfortable, so that in the matter of quarters the patients are well provided for. We do not mean to state by this that these quarters cannot be improved, but viewed in comparison with other portions of the building, notably such as are set aside for those concerned in the conduct and administration of its affairs, they are in excellent condition. The several pavilions standing on the grounds are very creditable, excepting those recently completed, such as the pavilion for erysipelas patients and the one for tuberculosis. Serious errors in design and construction exist in both, but they will no doubt fill passably well the purposes for which they were constructed.

The Marquand Pavilion, and its superstructure, continues to serve the excellent purpose for which it was erected, but here, as well as in other parts of the Hospital, we see the need for repairs so as to keep it in proper order and protect it from the ordinary wear and tear of exposure and use.

The Emergency Hospital.—The building outside the Hospital grounds used for lying-in cases is so utterly unfit for the purpose that your Committee can only condemn it in every particular. We are glad to report, however, that plans are in preparation by the Commissioner for converting a part of the building on these grounds, formerly used as a Medical College, into a suitable place for such cases.

The Dispensary.—The Dispensary has always been one of the greatest problems in the management of the Hospital. During 1900, 72,239 new patients were treated and 176,647 visits by patients, old and new, were received at this Dispensary. At the present time there is no direct supervision except of the most casual kind. Those left in charge are unfit to be in such a position and there is a general laxity of discipline and a non-observance of all rules that make it a jumble of good and bad service. It can best be described as being in a state of vicious decay, and only the most radical measures can keep it from being a discredit to the institution. It is essential that a paid Superintendent should be appointed who can remain on duty while the Dispensary is open and who can see that there is a proper distribution of patients, that there is an orderly condition of affairs in the Dispensary, and that the medical and other appointees attend to their work at the hours assigned and also be ready to decide the incessant petty disputes which continually arise; who can also see that the pilfering of bandages, drugs and instruments be made to cease, and the responsibiliy for such actions be placed where it belongs and instant suspen-

sion from duty be meted out to the wrong-doer.

The present method of the Superintendent of the Hospital making the rounds of the Dispensary for a few minutes at a time, in addition to all the other duties that he has to perform, is worse than useless for the proper administering of such an institution. A deputy or some one responsible to him for the care and conduct of the Dispensary, and who has absolute authority over those under him—subject to the approval of his superiors—is the only method that can bring anything like order out of the chaos that now exists. Your Committee speak thus positively on this subject for this method was tried a few years ago with great success.

Food.—We find that there is a lack of food of the right kind for patients recovering from severe illness. The very sick are provided for by the milk which is furnished in sufficient amount, but there is no adequate provision for the stages of convalescence, for the transition from a milk to a full diet. This can be made by increasing the *pro rata* allowance for the table, but in order to place it upon the right footing, we would suggest that a special Committee be appointed to inquire into the subject so as to fix the dietary as nearly as possible upon the same plane as was adopted by the Hospital in 1890.

Nurses.—In view of the criticisms which have recently been made of the Hospital, particularly of the nurses, this is a proper place at which to report upon that branch of the service. Outside the two pavilions, the Insane and the Alcoholic, it has been found satisfactory. This applies especially to the female nurses. For a time there was some strain owing to a deficiency in the supply of nurses of all kinds, male and female. This was most apparent in the night service throughout the hospital—including the Insane and Alcoholic Pavilions—contributing, no doubt, to the state of affairs which existed in these latter wards. The supply of nurses has, however, been recently increased so that no slackness or neglect can find excuse. With an adequate force of nurses on duty day and night, the Committee feels that this service is now upon a proper footing. One night nurse for each ward has been allowed, except in the Insane Wards, where three are recommended for night duty and four for day duty. The force of nurses in the Alcoholic Wards is also to be increased. The day nurses throughout the Hospital can be maintained at the present number, with additions in two or three of the male wards and perhaps one of the female wards. In order to facilitate the work of the male nurses, it is suggested that an Assistant Superintendent of nurses be nominated by the Managers of the Mills Training School, for each Medical and Surgical Division of the Hospital, and that the Commissioner be requested to sanction this arrangement.

The arrangement for the selection, instruction and discipline of the nurses which has heretofore existed, has led unintentionally to a division of responsibility in the government and control under which they work. In order to secure and develop the best material in both schools it is necessary that their fitness for the work and for the diploma of the school should be accurately determined. This compels the close supervision of a Superintendent of Nurses, one for each school, male and female, and necessitates instructors and examiners all under the direction of the Boards of Management of the two Training Schools. The bearing of this admirable system upon the nurses is unquestionably most excellent, but we suggest that, while the duties of those who supervise the nurses from the time of their admission to their departure from the school, be in no way curtailed, the Superintendent of the Hospital, as representing the disciplinary head of the institution as a whole, be placed in such control as will establish a more direct and short line of responsibility between himself and the nurses on duty than now prevails. The system of night reports which the present Superintendent has established, would appear to be an easy way of bringing this about, but he should have the right to suspend at once any nurse for cause. This need not interfere with the line of responsibility which runs from the nurse through the Superintendent of each School to the Superintendent of the Hospital, but it enables the Superintendent of the Hospital to act directly himself, in cases of conflict of opinion with these Superintendents, for his own judgment should dictate the proper conduct of the entire force of the institution under his control.

The Employees and Their Quarters.—The Committee now asks your attention to the problem presented in the character of some of the paid employees of the Hospital; many of whom are frequent inmates of the Alcoholic Pavilion. Those termed "help," who perform the menial service, are utterly worthless as a class. The reason for this is two fold, (1) insufficient pay; (2) unsanitary, poorly lighted, badly ventilated, crowded, and at times, dirty quarters. Quoting the report of the member of the Committee who gave special attention to this subject, we find that: "The dormitories for the male help are on the lower or ground floor. All these rooms are poorly lighted, with but few windows, and the ventilation is absolutely inadequate to the number of beds that have been crowded into them. The number of cubic feet of air to each occupant is far below what should be permitted.

Taking them in order: In the men's dormitory between the two prison wards, there are eighteen beds and the occupant of each bed has

been granted but about 480 cubic feet of air. And in the old alcoholic cells under Ward 29 the occupants have, in some instances, a little more air—about 1,000 cubic feet in some cases—but in others the amount varies from 500 to 300 cubic feet for each bed. The care of the rooms, beds and bedding has been left to some caretaker, who, so long as the external appearances were not too gross, allowed things to move pretty much as chance dictated. Proper care of the cleanliness and condition of these dormitories by those having authority over the housekeeping does not seem to have been exercised. The conditions are such that they violate several laws laid down by the Sanitary Code of the Health Department. Living under these conditions, it is small wonder these individuals add further to the discomfort of their fellows by frequently going in at night drunk and disorderly and increasing the disagreeable features of the place.

In one dormitory the caretaker had had tuberculosis for several years, and careful examination by members of the Medical Staff has shown that five out of seventeen of the inhabitants of this place have acquired tuberculosis since forced to live there; it is all the more striking that those who have acquired this disease are among those who have lived there the longest.

The dormitories for women are kept in a little cleaner condition than are those for the men. The dormitory over the Alcoholic Wards is better than the others because of the high gable of the roof, but its forty-seven beds are so crowded together that a generous estimate of the air space is but 500 cubic feet to each bed.

The help sleeping in these female dormitories under these conditions must necessarily be of a poor order: and here also drunken disorders and fights at night add to the discouragement of having any decent help in the Hospital.

The principle which has been insisted upon during the administration of the present Commissioner—that there should be paid help and thus responsible help about the Hospital—is the only right standard, but if the existing conditions of living in the cells and cellars of the Hospital or huddled together in large numbers prevails, it will be impossible to attain it. Proper help cannot be secured until these conditions are remedied, and at least a decent state of living is guaranteed to those who go there to work for their livelihood.

The present necessity which the Commissioner is under of utilizing as a dormitory the large dissecting-room in the building, used up to the present year as a medical college, but accentuates the above statement and shows the straits to which he is reduced in his endeavor to meet the absolute needs of this situation.

The class of employees engaged in the duties of stretcher bearers, who carry patients too ill to walk to and from the wards, is on a par for efficiency with the paid help, and largely from the same cause—those engaged as messengers, as attendants at the telephone, in the store-room, the laundry—and some of those doing clerical work are too often sufferers from some chronic ailment which makes it impossible for them to render proper service.

Question of Nurses.—Continuing our report upon the accommodations furnished those who are concerned in the service of the Hospital, we come next to those provided for the nurses. These are situated in the Mills Building and the Building of the New York Training School for Nurses, this latter being outside of the Hospital grounds and entirely independent of it and supported in part by a private fund furnished by its Board of Trustees. These two fine buildings, the gifts of private citizens, furnish adequate accommodations up to the present time. The increased number of nurses which our necessity demands, will however require a corresponding increase in these accommodations, otherwise conditions will speedily prevail in the quarters of the nurses which have proved such a serious drawback in the case of the resident House Staff of the Hospital, a matter of which we will now speak.

Quarters of House Staff.—In presenting the conditions which prevail in the accommodations provided for the House Staff, this all-important factor in the administration of any hospital, we desire to call your attention to the following:

The duties devolving upon the Staff of the several Divisions, medical and surgical, are greater and more complex than in any other hospital in the City. The service in the 32 wards of the main Hospital is at all times active. In addition the following services outside of the general wards are dependent for their proper care and supervision upon this same corps: Service in the Reception Office, in the Male and Female Prison Wards, in the Alcoholic Wards, in the Insane Pavilion, in the Emergency Lying-in Hospital, in the Tuberculosis Pavilion, in the Erysipelas Pavilion, together with ambulance calls, of which there were 4,616 during the year just ended.

The number of physicians and surgeons required for these extended duties is much greater than can be accommodated in the quarters available, so that in most of the rooms occupied by them as many as three must live continuously. The excess sleep in quarters which they provide for themselves outside of the Hospital grounds. During the day often late at night, they are at work in the Hospital, and of necessity must be accommodated in some measure somewhere; this can only be found in the already over-crowded rooms of their associates, hence it is that from five to six of these young men are not infre-

quently compelled to use one room in the intervals of their ward and other duties. The general sitting-room on the office floor is supposed to furnish this sort of accommodation for the Staff, but is used for so many different purposes that it is frequently not available.

A bare statement of this condition would seem to be sufficient to condemn it, but when we look further and realize that with three men sleeping in one room, and that in the discharge of their regular duties each is liable to be called up at least once during the night, making not infrequently as many as three interruptions a night for the entire room, the disadvantages are obvious. Add to this the impossibility of securing quiet in the face of the coming and going of five or six men who frequent the room during the day, and it appears that sufficient sleep is not always obtainable. This is a state of affairs incompatible with the highest grade of work in the extremely exacting position in which these men are placed. The sanitary condition of these quarters is only fair, the degree of cleanliness is what it should be, and as a whole, they are not what a great city should provide for men in its service who, without pay, are constantly facing the grave emergencies which a fight for the health, efficiency and life of its charges constantly present.

Conclusion.—We are of the opinion that the rules and regulations of the Hospital are correct upon the whole, that the various divisions and subdivisions of the force which is concerned in its administration are, as far as circumstances permit, organized upon correct lines. A division of authority has, however, existed which has been responsible for the defective execution of the laws under which the Hospital was supposed to live. This, as we stated to the Commissioner, some time ago, can be obviated by a head which places itself in contact with these various subdivisions and exercises immediate and vigorous control over all. We are glad to say he has accomplished this by installing Dr. Stewart.

But permanent improvement is rendered difficult and, some of us believe, impossible in the face of the inefficiency of the paid employees as a class, and the wretched accommodations furnished to so large a portion of your Staff, doctors and employees alike. Correct this and raise the *per capita* allowance of this Hospital to a figure approximating that which obtains in like institutions in this city and the crying evils will be permanently eradicated. Otherwise the outcome of this effort at improvement will end as the many which have preceded it. Decent service requires fair pay and decent accommodations. To which end we earnestly recommend an increase in the *per capita* allowance and also that the main Hospital building should be replaced at once by a modern and more commodious structure.

We beg to call your attention to the following comparative statement of the *per capita* allowance in this and other leading hospitals.

PER CAPITA COST PER DIEM FOR WARD PATIENTS.

St. Luke's Hospital	$1.82
Presbyterian Hospital	2.44
Roosevelt Hospital	2.195
Mt. Sinai Hospital (new hospital)	1.38½
New York Hospital	2.08
Pennsylvania Hospital (Difference in cost between N. Y. and Phila.)	1.17
Massachusetts General Hospital (Difference in cost between N. Y. and Boston)	1.96
Boston City Hospital	1.77
Bellevue Hospital	1.21

Selecting for comparison the five hospitals in the above list situated in New York City, it is seen that the average *per capita* allowance provided for each patient is $1.98, as against $1.21 for Bellevue Hospital; a statement all the more worthy of official consideration when we compare the commodious and well equipped quarters, in which their patients (18,907 in all) are cared for, with those at Bellevue Hospital in which we care for the 24,300 patients which fall to our lot.

VACCINATION, CLINICALLY CONSIDERED.[1]

BY FRANK S. FIELDER, M.D.,
OF NEW YORK;
ASSISTANT DEMONSTRATOR OF ANATOMY IN CORNELL UNIVERSITY MEDICAL COLLEGE; MEDICAL INSPECTOR IN THE NEW YORK CITY HEALTH DEPARTMENT.

It would be quite impossible in a paper of reasonable length to discuss exhaustively the clinical aspects of vaccination. I shall therefore wholly omit reference to some phases of the subject, and deal very briefly with others. Even so, I fear I shall tax your patience.

Clinical Course of the Normal Vaccinal Eruption.

The following description applies to primary cases vaccinated with virus of *high grade* efficiency.

Period of Incubation.—This lasts two or three days. Immediately after vaccination a small area of redness appears around the scarified spot. This subsides in a few hours. At the end of forty-eight to seventy-two hours; the second stage begins as a *papule*, which exists by itself for one or two days. The *vesicle* begins to develop by the end of the third or fourth day. Its first appearance and manner of growth vary according to the method used in performing the vaccination. If the virus has been introduced by *puncture*, the vesicle first shows at the site of puncture minute in size and quite round. Within a day or two it has became distinctly umbili-

[1] Read before the Section on Pediatrics of the New York Academy of Medicine, February 14, 1901.

cated, and is well raised above the surface of the skin. It increases in size until it reaches a diameter of $^3/_{16}$ to $^1/_4$ inch, and is rarely more than $^3/_8$ inch in diameter.

When the scarification method has been employed, vesiculation begins at one or frequently at two or three points around the edge of the scarified area. The vesicle then spreads until it forms a ring. If the scarified area has been of considerable size, the center is not covered by the vesicle, but is occupied by a depressed crust, which corresponds to the umbilication in a vesicle resulting from puncture. If the scarified area has been small, the vesicle will occupy this whole area, and will bear a small crust upon its somewhat depressed center. In either event, the greatest evidence of the process which finally results in the well-known scar is at the periphery of a ring-shaped vesicle; and it is by peripheral extension and the consequent broadening of this ring that the vesicle increases in size.

The shape of the vesicle depends upon that of the original scarification. If the latter is square the vesicle will be round; if oblong, it will be more or less regularly elliptical. When the virus has been inserted along double lines of scarification, small vesicles will appear along these lines; these will coalesce as the process advances, and the final result will be a compound vesicle of somewhat irregular outline.

When fully developed, about the sixth day after vaccination, the vesicle is of a pearly color, and is well distended, its edge rising abruptly from the papular base upon which it lies. Upon opening the vesicle, it is found to be composed of numerous cellular spaces, separated from one another by delicate walls, and containing a clear, very pale lymph.

Areola and Pustule.—On the seventh or eighth day, as a rule, the so-called areola appears. The skin around the vesicle becomes red and hot, for a variable distance, with a painful induration of the subcutaneous tissue. The erythema is often more extensive than the induration. The size of the areola and the extent of induration are very variable, but as a rule the circumference is not more than two inches from the edge of the vesicle. The color of the areola should be deep pink or bright red. Within a day or two after the first appearance of the areola, the vesicle changes to the so-called "pustule." If very pure virus has been used, this at first is often not true pustulation; the vesicle simply loses its translucent look, and becomes opaque, with perhaps a slight yellowish cast. Beneath the central crust there is a drop of pus, such as underlies the scab of any encrusted sore, but the contents of the vesicle are still serous, though the serum may be slightly turbid and contain a few leucocytes. If the vesicle contains bright yellow or greenish pus on the seventh day it may be considered infected. When the areola is at its height on the ninth to the twelfth day the adjacent lymph-nodes often become somewhat swollen and painful.

The formation of the areola and the pustulation are attended by a constitutional disturbance which varies according to personal idiosyncrasy, but which is usually proportionate to the extent and severity of the local inflammation. There is elevation of temperature, the child complains of itching and pain, and is restless and irritable, especially at night. There may be anorexia and more or less prostration. If there has been no septic infection, these symptoms are usually moderate, and subside in a few days—three days to a week. Some children escape them almost entirely. The pustule gradually increases in size, reaching its maximum from the eleventh to the thirteenth day; at this time its diameter is from $^1/_8$ to $^3/_{16}$ inch greater than that of the vesicle just before pustulation.

Desiccation and Cicatrization.—Sometimes the contents of the vesicle begin to dry up by the ninth or tenth day; usually, however, they turn to pus. Then, about the eleventh or twelfth day the areola begins to fade, the constitutional symptoms to subside, and the pustule to desiccate. A hard, dark scab is formed, which is shed from the eighteenth to the twenty-fifth day (oftenest about the twenty-first), leaving a pit-shaped depression. Upon this area a secondary scab often forms to be shed a few days later.

As regards constitutional symptoms, we may, roughly speaking, divide the vaccinal course into three periods of one week each: (1) A mild week of invasion and vesiculation, before the appearance of the areola; (2) a severe week during the existence of the areola, the swelling and the pustulation; throughout this period, pain, fever, anorexia, restlessness and irritability are likely to be marked; (3) a mild week, beginning with the fading of the areola, and the desiccation of the pustule, and ending with the shedding of the scab. During this week the constitutional symptoms subside *pari passu* with the subsidence of the local inflammation.

Variations in the Normal Clinical Course.

Early and Delayed Vesiculation.—Rarely the vesicle will appear on the second day. It is much more commonly delayed until the fourth, fifth, sixth, seventh, or even the eighth day, the subsequent history being apparently normal. Note is made of three primary cases observed by the vaccinators of the Health Department in which there was no vesiculation on the eighth day, and the cases were supposed to be failures; yet, at the end of ten days to two weeks, typical vesicles developed, which ran through the usual course and left typical scars. One of the cases mentioned was one of five test cases inoculated with a partic-

ular virus. The other four patients took well and ran through the customary course, while the fifth met with the delay above mentioned. In general, however, late vesiculation means virus of impaired activity.

Variations in Areola and Constitutional Symptoms.—The most notable variations that may be said to come fairly within the limits of a normal course are observed in the amount of areolar inflammation and in the intensity of the constitutional symptoms. A normal, uncomplicated vaccinia may run a mild or a severe course, just as does scarlatina, measles, varicella or variola.

If the vesicle is typical in appearance, and the areola, even if large and much indurated, is only a bright red, the condition may be regarded as normal, although severe; but if the vesicle is irregular in shape and hemorrhagic, or filled with very yellow or greenish pus and covered with a dirty looking crust, and if, moreover, the areola is of a livid purple near the edge of the pustule and dark red for a considerable distance away from it, the case is probably one of mixed infection. There is a sinister look about these infected cases which is quite characteristic. Cases in which the arm has been carefully cleansed before inoculation, and in which pains have been taken to prevent infection and to preserve the vesicle intact, present large and dark areolæ much less frequently than those in which such precautions are not taken. It is therefore fair to assume that such an areola is caused by infection other than pure vaccine infection. This extraneous infection may, of course, be due to impure virus or may be introduced from without at the time of vaccination or afterward.

Modifying Effects of General Ill Health, Skin Diseases, Hot Weather and Diarrhea.—Ill-nourished, bottle-fed and marasmic babies often respond atypically, or not at all to a virus which gives perfect results in healthy children. It is said that vaccination often fails to take typically in children affected with skin eruptions, especially eczema, but in the few eczematous children which I have vaccinated the disease has not appeared to modify the ordinary vaccinal course. It is also asserted that vaccination often fails when performed in hot weather, or upon children suffering from diarrhea. I have vaccinated many children on extremely hot days. Some had diarrhea at the time of inoculation and others developed it during the evolution of the pock, but neither the heat nor the diarrhea had apparently any influence in preventing the development of typical vesicles.

Raspberry Excrescence and Its Protective Power.—Quite frequently, when virus of a low grade of activity has been used, no vesicle develops, but there appears, instead, a hard, elevated excrescence, grossly resembling keloid, and in color like a fully ripe red raspberry. This elevation is not sensitive, no areola develops, no constitutional symptoms appear, and there is no evolution beyond that of the excrescence itself. This persists for some time, but is finally absorbed and disappears entirely, leaving no scar. The significance of this excrescence and its protective power are disputed points. Some hold it to be an abortive take, and claim for it some slight protective value, while others maintain that it affords no protection whatever. A certain number of such cases have been revaccinated as soon as the raspberry has been formed. In most of these the second vaccination has been successful. Sometimes typical vesicles have resulted, but more often the cases have run the course of a secondary vaccination instead of the typical course expected in true primary cases. In a few instances, repeated attempts to vaccinate have failed entirely, although virus was used which had resulted typically in all other cases tried. From these facts, the inference may be drawn that in some cases the raspberry excrescence does afford slight protection, at least against immediate revaccination. Occasionally raspberry marks and typical vesicles develop side by side, and sometimes a vesicle develops upon a raspberry base; but in the latter case the vesicle usually runs an abortive course. A raspberry excrescence is an evidence of poor virus. I have not seen one develop in a case of primary vaccination for two or three years.

Abortive Course.—In this, the vesicle appears early or late and never reaches full development; pustulation takes place early, and cicatrization follows before the end of the second week. This course is normal, although not invariable, in all vaccinations after the first. When it is observed in a supposed primary case, careful questioning usually elicits the fact that vaccination has been attempted before, but was supposed to have been a complete failure. A close examination of the arm will, however, usually discover a faint scar. If a true primary case runs an abortive course after vaccination with virus of unimpeachable quality, and if conditions such as seriously-impaired general health, or skin disease, which might possibly modify the course of the vaccination do not exist, it may be inferred that the individual is partially immune.

Complete Natural Immunity to Vaccination.—This is practically unknown, and those who have seen most vaccinations are least inclined to admit the possibility of its existence. The testimony of the vaccinators of the Health Department of this city, who have in some cases had an experience lasting over tens of years, and embracing hundreds of thousands of vaccinations, is that instances of complete natural immunity are extremely rare. The medical officer of the Local Government Board in England says that "from reports received from the Board's own vaccinators, covering a period of some fifteen years, and having concern

with no less than 95,077 consecutive primary vaccinations, it has been shown that no single case of insusceptibility has been met." There have been, however, during the century, many cases reported which have shown, to say the least, a remarkably refractory condition toward vaccination. In 1825 Spurgin reported three children as insusceptible to vaccination, and also insusceptible to variola with which he subsequently inoculated them.

I have seen one case which I was convinced was one of true idiopathic immunity. This was in the person of a physician of this city, who had been vaccinated many times, but always with absolutely no result. At one time during a considerable period he came frequently in contact with smallpox, but never contracted the disease. The most minute inspection of his arms, where all his vaccinations had been performed, failed to discover that any one of them had left the slightest mark. During the winter of 1895-96 I vaccinated him twice with two different specimens of Health Department glycerinated virus, both of which I had proved, by rigorous tests upon children, to be of more than usual activity. Both attempts were complete failures. In September, 1896, I made another attempt with unimpeachable virus. This also failed.

A curious case is now recovering from smallpox at North Brother's Island. The patient, a negro, was for many years a private in the United States Army. He had been vaccinated time after time by army surgeons at different posts, always without effect. He presented no scar. Recently he contracted smallpox which ran a severe course with a profuse, discrete eruption. Unfortunately, we are not certain of the efficiency of the virus used upon him; but it is to be inferred that his reputation as an immune would have led some of the surgeons who vaccinated him to be certain upon this point.

The Scar.

For several months after vaccination the normal scar is red and is usually depressed. Gradually it loses color, but is pinkish in the center for a year or more. Its final appearance in typical cases is as follows: In color it is whiter than the surrounding skin, the outline is quite regular, the edge sharply defined, and the entire area is slightly depressed, the center is smooth or somewhat striated, and is surrounded by a more or less deeply and numerously foveated ring. This ring corresponds to the area of active vesiculation; while the center represents either the original area of scarification, or the cicatrix following the separation of a more or less deep central slough. The shape of the scar depends upon the shape of the original scarification, while its size depends partly upon the size of the scarification, and partly upon the activity of the virus.

A poor scar is irregular in outline, with an ill-defined margin, no depression and with little or no foveation. Sometimes the scar is "poor" even when the vaccination has been a well-marked and typical course, but as a rule a good vaccination gives a good scar.

Complications.

Skin Eruptions, Infections, Generalized Vaccinia, Etc.—A monograph would be required to describe adequately all the complications which have been observed to follow in the train of vaccination.

In the old days of humanized virus, there was real danger of transmitting syphilis, and possibly tuberculosis. Now that bovine virus is almost exclusively used, the bugbear of invaccinated syphilis has disappeared. The possibility of inoculating tuberculosis is also extremely remote. Most of the vaccine laboratories now propagate their virus upon calves. Villain, chief of Meat Inspection in Paris, asserts that he has never seen a tuberculous calf between the ages of four and six months, among the 753,851 calves of this age killed in the abattoir during the years 1888-89-90. The calves used in the vaccine laboratory of the Health Department of this city, carefully selected in the first place, are killed immediately after the collection of the virus, and their organs carefully examined by a veterinarian for evidences of disease, with the idea of rejecting the virus if disease is found. For several years, to my certain knowledge, no virus has been rejected because of tuberculosis in the animal. The inoculation of syphilis or tuberculosis, then, need no longer be feared.

Allbutt, in his System of Medicine, gives an elaborate classification of the rashes and infections which may complicate the course of vaccinia. I have space to mention only a few of those most frequently seen.

Skin Eruptions.—These usually develop about the time the areola appears, but may develop earlier. By far the most frequent of these is a *roscolous rash* which often quite closely resembles measles or the eruption which so frequently follows the injection of diphtheria antitoxin. The roseolous patches, small or large, may be distributed over most of the body. In some instances the eruption seems entirely non-inflammatory, and is attended by little or no itching or constitutional disturbance. In other cases itching is severe. In either event the rash subsides in two to four days without treatment.

Erythema Multiforme.—Another fairly common rash follows some one of the types of erythema multiforme. For instance, there will be a more or less general distribution of erythematous patches, ¼ to ¾ inch in diameter, with a small vesicle in the center of each patch. There is considerable itching, the vesicle is soon destroyed by scratching, and a bloody crust is formed which promptly dries up. The patch fades, leaving a faint pigmen-

tation which persists for some time. The eruption may be attended by moderate constitutional symptoms.

Scarlatiniform Rash.—This sometimes appears and may present a very perplexing problem in diagnosis. In a recent private case of my own such a rash appeared on the fifth day after vaccination. The child had a little fever and the tongue and throat were red. Neither the diagnostician of the Health Department nor myself could make a positive diagnosis. The rash disappeared within twenty-four hours, as it often does in mild scarlatina. Desquamation did not take place, and it was only upon this feature, after a ten days' quarantine, that the diagnosis of scarlatina could be finally excluded.

Eczema.—It is asserted that vaccination is often followed by an outbreak of eczema, especially in a person who has had this disease at some previous time; and that, as a rule, an eczema existing at the time of vaccination is made distinctly worse. I have vaccinated numerous eczematous children, but have not observed that the disease was thereby aggravated; nor have I observed the lighting up of an old eczema which at the time of vaccination was inactive.

It is also held that there is danger of causing generalized vaccinia by auto-inoculation over the eczematous area, but this must be of rare occurrence, for at the Hôpital Saint Louis in Paris, for several years, all the dermatological cases were vaccinated, and yet only one case of generalized vaccinia appeared.

Infections.—*Septicemia* of virulent and even fatal type has been observed, though rarely. Many of the cases reported have occurred in groups, following the use of particular specimens of humanized virus.

Cellulitis, or Dermato-Cellulitis.—Some degree of localized septic infection is the commonest of all the complications. This may be of any grade of severity, from an inflammation which is scarcely more intense than that seen in a severe normal case, up to the most virulent form of gangrenous cellulitis, with suppuration of the adjacent lymph-nodes and grave constitutional disturbance. Fortunately, very few cases pass beyond the stage of a moderate cellulitis, with some sloughing at the site of the vesicle, and a more or less marked non-suppurative axillary (or inguinal), adenitis. Such cases demand, and usually respond kindly to treatment upon general surgical principles. I have seen only two cases of suppurative adenitis.

Erysipelas.—This is said to be a fairly frequent complication. The dividing line between this disease and cellulitis is a very indefinite one, both bacteriologically and clinically, and it is sometimes difficult to decide whether a particular case is one of erysipelas or of local dermatitis and cellulitis due to ordinary pyogenic infection. The classical distinctive features of erysipelas are as follows: The inflammation extends widely and rapidly, and is most intense at its spreading edge; vesicles form on the surface of the affected skin; resolution takes place just at the point first attacked, and is attended by considerable desquamation. If only such classical symptoms be regarded as erysipelas, I have observed no instances of this disease after vaccination. The brilliant blush upon the skin which is seen in many cases of infected vaccination, frequently suggests erysipelas, but in these cases the inflammation does not extend very rapidly or very widely; it almost never goes beyond the affected limb; it is most intense in the immediate vicinity of the vesicle, and continues to be most intense there; vesicles do not form upon the skin, except perhaps a few in the immediate vicinity of the vaccinated spot; resolution takes place first at the periphery of the inflamed area, and last at the point first attacked, and is not attended by desquamation. True erysipelas complicating vaccination is certainly rare at the present day.

Impetigo Contagiosa.—Sometimes this occurs as a complication. Two cases observed by the writer were already well developed on the sixth day after vaccination. In one, a lesion of impetigo was situated at the site of each of the three inoculated spots, and there was a patch of the disease on the back of the infant's neck. In the other infant, the eruption was confined to the lower part of the back, and may have been only a coincidence, although no skin lesions had existed before vaccination. Constitutional symptoms were insignificant in each case. The same virus was used on both children. In no other cases vaccinated with this virus did impetigo or any other eruption appear.

Tetanus.—This is a rare complication. Huddleston, in an examination of the literature found only 12 cases, 11 of which were fatal in periods varying from three to fifteen days.

Delayed Healing After Shedding of Scab.—In some infected cases, and also in some which have run an apparently normal course, an indolent ulcer follows the shedding of the scab, or the spot is covered with flabby exuberant granulations. Untreated, these cases often remain unhealed for months. Frequently these spots heal temporarily, but the cicatrix is of such low vitality that it breaks down repeatedly, and the case may go on for months alternately healing and breaking down, unless appropriately treated by the physician.

Generalized Vaccinia.—By this is meant, not the appearance of a few supernumerary vesicles near the site of vaccination, but an eruption passing through the successive stages of papule, vesicle and pustule, which comes on within a few days after vaccination, and which is diffused more or less extensively over the body.

The cause of generalized vaccinia is disputed.

Some authors claim that every case is an auto-inoculation, and certainly, in many instances, this is an adequate explanation of the presence of the additional lesions. Five such cases have come under my own observation. In one case, two vesicles appeared side by side just above the wrist of the vaccinated arm. The child had gotten some of the blood and vaccine mixture upon her right hand, and had rubbed it upon her left wrist. The mother had wiped the wrist with a cloth but had not washed it. The extra vesicles were as far advanced when inspected as the original ones. This was an unquestionable case of auto-inoculation. In another case the struggling child was accidentally pricked upon the back of the hand with the still-charged lancet immediately after vaccination. In spite of washing a vesicle developed. In a third case, a vesicle developed upon the cheek on the same side as the vaccinated arm, due, doubtless, either to infection by means of the finger-nails, or to actual contact of the cheek with the vaccinated spot. In the fourth case, four vesicles appeared; one on the left forearm (the vaccinated side), one on the right forearm, one on the right upper arm, and one on the left thigh. This was on the seventh or eighth day after vaccination, when the original vesicle was already well developed and surrounded by an areola. The new vesicles were soon broken by scratching, and their progress, therefore, could not be accurately followed, but they seemed to run the short course of a secondary vaccination. No positive history of auto-inoculation could be obtained in this case, but as the child could easily have infected himself without the knowledge of his parents, and as the lesions could easily be explained on the auto-inoculation theory, there would seem to be no reason for postulating a systemic infection. Inspection of this case six months after vaccination showed rather poorly marked scars at the sites of the supernumerary vesicles.

The fifth case was clearly one of auto-inoculation. The child scratched its arm, and rubbed its eyelid with the infected fingers. As a result there developed three vesicles, one on the upper lid and two on the lower, just where their edges came together in closing the eyes.

Cases of true generalized vaccinia, however, do occur. Chauveau produced the condition experimentally by injecting virus into a lymphatic.

Huddleston has collected, from the literature, 45 cases of generalized vaccinia with 7 deaths. Of these cases, 12 could reasonably be explained on the theory of auto-inoculation, and in 13 more such a cause was possible, though not probable. In the remaining 20 cases, no such cause could be reasonably claimed, and a diffusion of the virus by the blood or lymph channels was apparently a necessary explanation.

The diagnosis of generalized vaccinia, usually easy, may be difficult. Varicella, miliaria, or a simple vaccination rash of vesicular type may present characters which strongly resemble generalized vaccinia. In such a case the doubt may be removed by taking lymph from a vesicle at a distance from the site of vaccination, and inoculating another subject with it. If the case is one of generalized vaccinia, a true vaccine vesicle will of course, develop.

Immunity Conferred by Vaccination to Smallpox and Revaccination.

Immunity to revaccination or to smallpox through the medium of vaccination is acquired rather slowly. Repeated experiments by vaccinating a subject daily until the vaccination fails to take have shown that immunity is secured usually in from seven to ten days, more rarely not until a few days later.

The incubation period of smallpox varies, but is usually eleven to fifteen days. If a person is vaccinated on the day of exposure, or even on the next day, he is likely to escape the disease altogether, but may have varioloid. In case smallpox develops during the evolution of the vaccine pock, the following facts are likely to be observed: If the smallpox eruption appears before the vaccination has reached the stage of areola (eight to ten days), the disease will not be much modified, but the vaccination vesicle will quickly dry after the disappearance of the eruption—in other words, the smallpox will modify the vaccination. If the vaccination has reached the stage of fully developed areola by the time the smallpox eruption appears, the disease will be mild, and evidently modified by the vaccination.

Immunity Is Not Interfered With by the Destruction of the Vaccine Vesicle.—Bosquet proved this by the following experiment: on the fourth day after vaccination, he destroyed with the lancet and with nitrate of silver the papules which had begun to be visible, but immunization occurred just the same as if the vaccinal eruption had been allowed to follow its normal course.

Aimé Martin destroyed the skin with Vienna paste at the point of inoculation before the appearance of any papule, and subsequent inoculations showed that immunity had already been acquired. In cows, Maurice Raynaud excised discs of skin including the points of inoculation, twenty-six hours after the operation. There was no trace of a cutaneous eruption, but the animals were immune to revaccination two weeks later. In the laboratory of the Health Department of this city it was found that in calves immunity was not secured unless two days were allowed to elapse before the excision was practised; but all experimenters agree that after the vesicle has appeared, its destruction does not prevent immunity. Chauveau found that the injection of vaccine virus into the lymphatics or veins caused a general eruption with resulting immunity, without, if proper precautions were taken, the development of the local lesion at the point of injection.

The local lesion, then, is not requisite in

order that the immunizing substance, whatever it is, may be produced in the system. I emphasize this point, because many physicians hesitate to open and cleanse an infected vaccine vesicle for fear this measure may lessen the degree of protection afforded by the vaccination.

The mechanism of immunity is still unexplained. We only know that the infusion of serum from vaccinated animals, during the stage of eruption into unvaccinated animals, has shown that the vaccinogenous substance is present in the blood during this stage. It is there, however, in comparatively small proportion, since it is necessary to infuse large amounts, nearly $^1/_{100}$ of the body weight, in order to secure immunity to subsequent vaccination.

Effect Upon the Fetus of Vaccination or Smallpox in the Mother.—Little or no immunity is given the fetus by vaccinating the mother. Wolf vaccinated 17, and Gast vaccinated 10 women in various stages of pregnancy, and subsequently vaccinated the children with complete success. Behm, after successfully vaccinating 63 pregnant women, found 12 of the children refractory to the first vaccination, and of these 12, two were afterwards successfully vaccinated, one in the second month, and one at the end of a year. Dubiquet obtained 44 "takes" in 50 cases of new born children, whose mothers had been successfully vaccinated during pregnancy.

Variola in the pregnant woman does not confer immunity upon the child. In fact the fetus *in utero* may be attacked and the child be born with the active eruption, or with the scars of the completed disease.

Children born while the mother has smallpox usually contract the disease. If the mother is in the early stage of the disease at the time the child is born and if the infant is vaccinated at once it *may* escape. As a rule, however, a portion of the incubation period has elapsed before birth, so that the eruption appears before immunity can be secured by vaccination and the infant dies of the disease.

Duration of Immunity Conferred by Vaccination.—The duration of immunity, both to smallpox and to revaccination, is extremely variable. For a period after Jenner's epoch-making discovery it was believed that the vaccinated person was thenceforth always protected against smallpox; but the history of many epidemics has proved the fallacy of this belief, and it is now generally recognized that permanent immunity is of rare occurrence. In general it may be said that a severe case of smallpox is rarely seen within ten years of a successful vaccination; and that within five years, very few cases even of varioloid occur. Dillingham states that he has seen but one case of smallpox follow a successful vaccination within as short a time as five years. This was a very mild case of varioloid, vaccinated five years before. Not more than twenty lesions were present on the entire body.

There is now at North Brother Island a man, twenty-four years of age, who was once successfully vaccinated in childhood and again two years ago. The scar of this last vaccination is of good size and quality for a revaccination scar. The patient has a very mild attack of varioloid with about eighty lesions. This patient's wife, eighteen years of age, was also successfully vaccinated in childhood, and again two years ago. She is in the hospital with a mild case of varioloid.

In exceptional instances, neither smallpox nor vaccination appear to confer protection either against subsequent attacks of smallpox or against revaccination. Brouardel reports the case of a woman, thirty-two years of age, whom he saw in 1868 suffering from confluent variola. In 1871 she had an attack of discrete variola. In 1873 he vaccinated her, and was surprised to find that it took perfectly. Thereafter he revaccinated her six times at intervals of six months, and each time the vaccinal eruption appeared with absolute regularity.

Allbutt reports the case of a woman who had smallpox three times and was three times successfully vaccinated. She was born in 1858. Her mother had smallpox when the babe was eight days old and the child took it in mild form. At the age of three months she was successfully vaccinated, three scars resulting. In 1881 she was successfully revaccinated—two scars. In 1883 she had a second mild attack of smallpox. In September, 1892, she was successfully revaccinated for the second time. In November, 1892, and in 1893 vaccination failed. In 1896 she had a third very mild attack of smallpox.

With reference to the duration of immunity following vaccination, Wm. M. Welch has attempted to determine at what age after primary vaccination any considerable number of persons contract smallpox. He has compiled the following table from the records of the Philadelphia Smallpox Hospital.

TABLE I.

UNDER 1 YEAR.

	Cases.	Deaths.	Per cent. of Deaths.
Unvaccinated	89	60	67.41
Vaccinated	2	0	0
1 TO 7 YEARS.			
Unvaccinated	467	221	47.32
Vaccinated in infancy—good scars	11	0	0
" " " fair "	10	1	10
" " " poor "	15	1	6.66
Total number vaccinated	36	2	5.55
7 TO 14 YEARS.			
Unvaccinated	242	72	29.75
Vaccinated in infancy—good scars	55	2	3.63
" " " fair "	23	2	8.69
" " " poor "	59	9	15.25
Total number vaccinated	137	13	9.48
14 YEARS UP.			
Unvaccinated	1,111	693	62.37
Vaccinated in infancy—good scars	1,406	122	8.67
" " " fair "	664	96	14.45
" " " poor "	1,027	286	27.84
Total number vaccinated	3,097	504	16.27

This table shows that the protection afforded by vaccination in infancy fails rarely before seven years of age, fairly often between seven and fourteen years and very often after fourteen years. It is evident, then, that in the presence of an epidemic the general rule that a successful vaccination will hold good for five or seven years is not to be relied upon.

Variability of Immunity.—In 1856, Lalagade, in a statistical study of 2,201 cases of revaccination, found that in children from five to ten years of age, revaccination was successful in only 8.75 per cent. of the cases; that between the ages of ten and thirty-five, the percentage of success was about 50; and that after thirty-five years the receptivity rapidly diminished. Unfortunately it is not stated whether the virus used in these tests was of proved efficiency. I note this startling omission in almost all reports. This may account for the discrepancy between Lalagade's results and those of the school vaccinators in this city. The virus which they use is rigidly tested upon primary cases before it is placed in their hands. Their reports show that at least 75 per cent. of the children in the primary and grammar school grades are susceptible to revaccination. In some schools in which revaccination has not been recently performed, the success has been above 95 per cent.

Short Duration of Immunity.—The duration of immunity to revaccination may be very short; and probably is short in a much larger proportion of cases than has been suspected, for the operation is seldom performed within one or even two years after a previous successful vaccination. Buchanan has reported a series of cases occurring in prisoners, in which successful vaccination followed closely upon a previous success. Four cases were in less than one month, nine cases between one and two months, four cases between two and three months, and twelve cases between three and six months.

At North Brother Island, where all patients are vaccinated upon arrival, it has happened that persons sent there repeatedly have been repeatedly vaccinated with success. In two instances success has followed within six months after the first vaccination. There are now at the Island eleven children between the ages of two and one-half and five years upon whom revaccination is "taking." In only one instance is the scar of the primary vaccination a faint one. The others all present good primary scars.

Three or four years ago, I myself made the following test upon 10 children. I performed the primary vaccinations by puncture in four spots each. Each case took typically in all four spots, and I exhibited them before a medical society in illustration of a paper upon methods of vaccination. Nine months later, I revaccinated all of these children in one spot each. Three of them "took," though they ran a mild course. Six days ago I revaccinated 20 children who were first vaccinated 4 months ago, with good takes and good resulting scars. Inspection to-day shows that 4 of these children are "taking," each showign a distinct though small vesicle which will evidently run an abortive course. This, in spite of the fact that control tests of the virus showed it to be of only moderate activity.

As regards susceptibility to revaccination the quality of the scar is an untrustworthy guide. Persons exhibiting poor primary scars are sometimes exceedingly refractory to revaccination; on the other hand it is very frequently possible successfully to revaccinate persons who present fairly recent scars of good quality. It is evident, therefore, not only that vaccination does not confer permanent immunity to revaccination, but that we can never be sure in a given case how long the immunity will last.

The immunity conferred by vaccination against revaccination is often of shorter duration than that which it confers against smallpox; in other words, a person may be successfully revaccinated while he is still immune to smallpox. Edward Jenner discovered this fact very early, and showed that among persons immune to smallpox both by exposure and by inoculation, natural cowpox might be induced again and again. It has already been shown that revaccination is often successful within five, or even two, years after a previous successful vaccination; yet it is well known that the number of cases of smallpox which occur within a similar period is very small.

Sir John Simon in his "Papers Relating to the History and Practice of Vaccination," after showing that 14,384 soldiers had been revaccinated with a success of 33 per cent., says: "Is it a legitimate inference that if these 14,384 soldiers had been exposed to smallpox every third man would have caught the disease? Certainly not. The inoculation of lymph is, so to speak, a finer and more delicate test of susceptibility to the smallpox poison than is the breathing of an infected atmosphere; so that many persons, when the lymph of cowpox is inserted in their skins, will give, locally at least, evidences of susceptibility which no atmospheric infection would have elicited from them. The success of vaccination after remote smallpox is also at least 33 per cent., whereas, notoriously, of persons who have once had smallpox not nearly one-third become afterward capable of contracting the disease again by frequenting the neighborhood of the sick."

A somewhat remarkable instance of an individual immune to smallpox but susceptible to vaccination, is found in the person of the present Resident Physician at North Brother Island. He was successfully vaccinated in childhood, a good scar resulting. A few years ago revaccination took poorly, leaving no scar. At the Island up to last August he had been vaccinated many times with no effect. For the past three and one-half months he has been in daily, intimate contact with the two hundred odd cases of smallpox which have been under his care, a very severe test of his immunity to the disease; yet ten days ago, seven months after his last attempt, he was vaccinated successfully. A distinct vesicle appeared at the

end of three and one-half days. An areola formed, and the pock ran through the short course of a reasonably good secondary "take," desiccation being nearly complete at the end of a week.

What Constitutes Efficient Vaccination?—The most efficient vaccination may be defined as that which secures to those vaccinated: (1) the smallest proportion of smallpox cases per thousand individuals; (2) the longest duration of immunity among those who finally take smallpox; (3) the lowest mortality among those who contract the disease; (4) the mildest course of the disease and the least amount of subsequent pitting, among those who, having had smallpox, survive it.

In performing vaccination, how many insertions of virus, and what sort of resulting scars are necessary to afford the most complete protection as judged by the above standard?

1. With reference to the proportion of smallpox cases per 1,000 individuals, Dr. E. C. Seaton and Dr. Buchanan made observations, during the smallpox epidemic in London in 1863, upon more than 50,000 persons. Some of these had never been vaccinated, but most of them had been vaccinated in various manners and degrees. Their results appear in the accompanying table:

TABLE II.

		No. Marked with Smallpox per 1,000. 360
1. Having no vaccination scars.		
2. Vaccinated.		
(1) Number of scars		
	(*a*) one scar	6.81
	(*b*) two scars	2.49
	(*c*) three "	1.42
	(*d*) four or more scars	0.67
(2) Quality of scar or scars		
	(*a*) bad quality	7.60
	(*b*) tolerable "	2.35
	(*c*) excellent "	1.22

From this table it appears that the smallest proportion of persons who had had smallpox per 1,000 of persons examined was among those who had been vaccinated in four or more spots and among those who presented scars of excellent quality. As regards the smallpox pitting displayed, without quoting actual figures, the observers noted that the well vaccinated were more lightly marked than the poorly vaccinated.

2. With reference to the duration of immunity to smallpox following different methods of vaccination, R. Cory made observations between the years 1884 and 1887. To avoid the possibilty of error in diagnosis only those cases which were pitted were considered. Of such cases there were 448. The ages at which these persons developed smallpox are shown in the following table:

TABLE III.

	No. of cases.	Average age in years.
Unvaccinated	210	6.58
Alleged to have been vaccinated—no scar	105	9.86
Vaccinated		
1 scar	47	17.77
2 scars	31	17.82
3 "	33	18.02
4 "	12	18.67
5 or more scars	10	19.03

This table, so far as it goes, seems to show that vaccination by multiple insertion gives slightly longer immunity to smallpox than does the one spot method; but the number of cases in each class is too small to give much authority to the table.

3. With reference to the mortality rate in cases of smallpox which have followed vaccination by different methods, it is possible to quote figures covering large numbers of cases.

Gayton, in the Report of the Royal Commission on Vaccination 1889-90, gives the following table upon 7,415 cases of post vaccinal smallpox.

TABLE IV.

No. of Vaccination Scars.	No. of Cases of Smallpox.	Per cent. of Deaths.
1 scar	2,289	5.4
2 scars	2,464	3.6
3 "	1,424	3.1
4 "	1,238	1.6

It is to be understood with reference to this and to the following tables that the columns headed "Numbers of Scars" means the scars resulting from primary vaccination and not the scars of successive vaccinations at different times. This table points strongly toward the conclusion that vaccination by multiple insertion gives better protection than the single spot method.

J. F. Marson, for more than thirty years the Resident Physician of the London Smallpox Hospital, made very careful observations on the number and quality of the scars in all the cases of post vaccinal smallpox which came under his care. During the sixteen years from 1836 to 1861 3,094 cases of smallpox were treated in the hospital. Excluding 63 cases of death from smallpox complicated by other diseases in themselves fatal, he compiled the following mortality table:

TABLE V.

		Per cent of Deaths	
1. Never vaccinated		35.5	
2. Alleged to have been vaccinated—no scar visible		21.7	
3. Vaccinated.			
1 scar	good quality	4.23	7.57
	indifferent quality	11.95	
2 scars	good quality	2.68	4.13
	indifferent quality	7.29	
3 scars	good quality	1.63	1.85
	indifferent quality	2.32	
4 or more scars	good quality	0.99	0.74
	indifferent quality	0.00	

TABLE VI.

Average mortality of all post vaccinal cases	6.76
" " " " 1 and 2 scar cases	6.21
" " " " 3 and 4 " "	1.30
" " " " good " "	3.04
" " " " indifferent scar cases	9.77

From these observations, Marson deduced the law that the efficiency of vaccination is in the exact ratio of its excellence and completeness as shown by the number and quality of the resulting scars.

During a second period of sixteen years, from 1852 to 1867, Marson continued his observations, the number of smallpox cases treated being 10,661. The results were as follows:

TABLE VII.

		Per cent. of Deaths.
1. Never vaccinated		34.9
2. Alleged to have been vaccinated—no scar visible		39.4
3. Vaccinated—1 scar		13.8
	2 scars	7.7
	3 "	3.0
	4 or more scars	0.9

The percentages in this table differ somewhat from those in Marson's first table, but they point with equal emphasis to the superior efficiency of vaccination by multiple as compared with single insertion.

W. M. Welch, who for twenty-five years was in charge of the Philadelphia Smallpox Hospital, from a similar study of his cases, confirms Marson's view that the protective degree of vaccination can be measured to a considerable extent by the quality of the scars borne by the vaccinated persons. His experience, however, does not entirely agree with Marson's as to the relative value of multiple as compared with single insertion. The following is Welch's table:

TABLE VII.

	Cases.	Deaths.	Per cent. of Deaths.
Vaccinated	1,668	909	54.49
Alleged to have been vaccinated—no scar visible	258	150	58.13
Vaccinated during incubation of smallpox			
From 1 to 7 days before appearance of eruption	59	25	42.37
Longer than 7 days before appearance of eruption	95	17	17.89
Vaccinated in infancy—one good scar	820	70	8.58
" " " " fair "	451	70	15.52
" " " " poor "	874	256	29.29
Total number showing 1 scar	2,415	396	18.46
Vaccinated in infancy—two good scars	287	20	6.97
" " " " fair "	114	14	12.28
" " " " poor "	102	24	23.53
Total number showing 2 scars	503	58	11.53
Vaccinated in infancy—three good scars	122	10	8.19
" " " " fair "	49	4	8.16
" " " " poor "	51	13	25.49
Total number showing 3 scars	222	27	12.16
Vaccinated in infancy—four or more good scars	251	24	9.56
Vaccinated in infancy—four or more fair scars	81	10	12.34
Vaccinated in infancy—four or more poor scars	97	11	11.34
Total number showing 4 or more scars	429	45	10.49

Summarizing the post-vaccinal cases with reference to the quality of the scars we have

	Cases.	Deaths.	Per cent. of Deaths.
Vaccinated in infancy—good scars	1,480	124	8.38
" " " fair "	695	98	14.10
" " " poor "	1,124	304	27.04
Total number of post-vaccinal cases	3,299	526	15.90

An examination of this table shows that the protective power of vaccination is in proportion to the excellence of the resulting scars. As regards number of insertions, the table shows that one good scar protects better than two, three or four fair or poor scars, and practically as well as two, three or four good scars. Welch thereupon concludes that the quality of the scars following vaccination is a far more reliable indication of the degree of protection than the quantity, and that when the scars are typical it makes no difference whether they are single or multiple.

If, however, we compare the total number of cases vaccinated by the different methods, we get from Welch's own table figures which speak for the superiority of vaccination by multiple insertion. Thus:

TABLE IX.

	Cases.	Deaths.	Per cent. of Deaths.
Total number showing one scar	2,415	396	18.46
" " " two scars	503	58	11.53
" " " three "	222	27	12.16
" " " four or more scars	429	45	10.49

Taking the extremes of the table we have the mortality of the one scar cases 18.46 per cent. while that of the four or more scar cases is only 10.49 per cent.

4. As regards the severity of smallpox in patients who have been vaccinated by different methods and with different grades of resulting scars, Marson in his first series of cases found that (*a*) *as to number of scars*, of 2,245 patients with 1 and 2 scars, 392 or 17½ per cent. had confluent smallpox; of 542 patients with 3, 4 and more scars, 36 or only 6½ per cent. had confluent smallpox; (*b*) *as to quality of scars*, of 1,765 patients with good scars, 196 or 11 per cent. had confluent smallpox; of 1,022 patients with indifferent scars, 232 or 22 per cent. had confluent smallpox.

From all this evidence it seems fair to conclude with Marson, that "test the question in which way soever we will, the result is in favor of producing four vesicles, at least, at vaccination, with lymph which leaves good permanent cicatries."

Revaccination.

Husson and Bousquet, of Paris, believing that the existence of post-vaccinal smallpox was to be explained upon the theory that the immunity afforded by vaccination was after a time lost, were the first to recommend general and systematic revaccination. *That revaccination restores lost immunity is proved* by an overwhelming mass of evidence. It will be sufficient to cite a few figures. Revaccination was first extensively practised in the Prussion army; from 1834 to 1848, out of 425,000 soldiers revaccinated, 46.58 per cent. were successful. In these fourteen years there were but 77 cases of variola and varioloid in the army, and among them not a single death. In 1843, smallpox was epidemic in Prussia, yet in the entire army there were but 12 cases. In Würtemberg, in the early days of revaccination, among 14,284 revaccinated soldiers, only one case of smallpox appeared in five years. Among 26,964 revaccinated civilians, but five cases of smallpox appeared during the same period. During the Franco-Prussian war the German army, numbering 1,000,000, vaccinated and revaccinated men, lost only 459 men from smallpox during the years 1870 and 1871; while the French army, far less numerous, where revaccination was not compulsory, lost 23,400 men from this disesase in the same period.

Again, in Prussia, the mortality from smallpox in 1835 was 27 per 100,000; in 1872 it was 262. In 1874, vaccination and revaccination became obligatory, and the mortality fell at once to 3.6 per 100,000. In 1886 there were 107 deaths from smallpox in the entire German Empire, or

only 0.39 per 100,000. In 1888, with an increased population, the number of deaths had fallen to 110 for the whole year.

Even more significant is the evidence of the smallpox hospitals. Marston states that in thirty years few smallpox patients were admitted who had been revaccinated with effect; and these had very mild varioloid. Among the nurses and attendants, not one who had been revaccinated contracted the disease. Wm. Welch in an experience of 25 years at the Municipal Hospital of Philadelphia found that no physician, nurse or other employé who had been revaccinated before commencing duty developed smallpox or varioloid.

The proposition that *revaccination protects as fully as a previous attack of variola* is proved by the following figures, which I quote from Le Fort: In 1887, in Sheffield, there were 18,121 persons who had already had smallpox, and of these 23 contracted the disease again, that is to say, a proportion of 1.3 per 1,000. Of 63,354 revaccinated individuals, 75 contracted smallpox, a proportion of 1.1 per 1,000.

By the statistics of the same epidemic, this author showed that *a successfully revaccinated person is much better protected than one who has been but once vaccinated;* for, while revaccinated persons contracted smallpox in the proportion of only 1.1 per 1,000, those who had been but once vaccinated contracted the disease in the ratio of 230 per 1,000.

It is evident therefore that if we would preserve vaccinal immunity, revaccination should be performed as conscientiously as primary vaccination. In the absence of an epidemic, this may be postponed until the child is of school age; but if smallpox becomes prevalent it should be performed at once even if the primary vaccination was of recent date.

While it is important that the primary vaccination should be performed in such a way as to give the highest degree of protection, we must remember that after a variable number of years immunity derived from the most efficient primary vaccination is lost. There is no doubt that an adult who was successfully vaccinated in infancy and again at puberty by the one spot method, is much better protected than one whose primary vaccination was performed by multiple insertion, and who has not been revaccinated.

The character of the eruption in revaccination is usually different from that observed in primary cases.

Instances are sometimes met with in which the immunity resulting from the first vaccination has been so completely lost that the pock of the revaccination presents the typical characters of a primary case; but I think the school vaccinators, whose experience in revaccination runs into the hundreds of thousands of cases will confirm the assertion that this is not often so.

As a rule the eruption is at no time so purely vesicular as in a primary case, the pustule and the areola develop earlier, and desiccation is complete at a correspondingly early date; so that, often, a successful revaccination has already cicatrized and shed its scab by the end of the second week. The resulting scar is likely to be small, faint and poorly marked. Some cases, however, starting as above, do not dry up quickly, but pass into a stage of more marked inflammation and more severe constitutional symptoms than are usually seen even in severe primary cases.

Instances of very long periods of incubation after revaccination are also reported—the vesicle not appearing until the 10th, 14th, 18th or even 30th day. Persons whose immunity has been but partially lost present marked modifications of the typical vaccinal eruption. To this class of cases, Trousseau and Dumont Pallier, in 1860, gave the name of "vaccinoid," a condition bearing the same relation to vaccinia that varioloid bears to variola. Hervieux accepted this view, and demonstrated in 1893 that vaccinoid transmits by inoculation true vaccinia, and that, like vaccinia, it confers protection against smallpox. Hervieux describes three types of vaccinoid, dependent upon the extent to which the weakening of the immunity has advanced: (1) At the point of inoculation there appears a pink papule, hardly at all elevated above the surrounding integument, and without any areola; it disappears at the end of a few days, leaving no scar. (2) There forms an acuminate papule, larger than that seen in the first type of vaccinoid, redder, more distinctly visible, surmounted by a little vesicle at its point, surrounded by a faint areola, and leaving after desiccation a little scab which falls soon without the formation of a cicatrix. (3) The vesicle is more distinct, the areola is more pronounced, the scab is larger and more adherent and leaves behind it a cicatrix, which, however, disappears in the course of time.

Poor virus will often give a vaccinoid eruption in cases which will respond more nearly typically to virus of high grade activity. This "false vaccinoid," if such an expression may be used, cannot be depended upon to confer complete immunity. In deciding on the value of the result obtained in any given case of revaccination, therefore, the physician should be sure of the efficiency of his virus. It is too often the case that one is lulled into a false sense of security by a vaccinoid pock, due not to partial immunity but to poor virus.

The character of the eruption, then, in revaccination depends upon the degree of immunity conferred by previous vaccination, and upon the quality of the virus employed. If high-grade virus has been used, (*a*) failure shows that the subject is still immune; (*b*) vaccinoid completes a previously partial immunity; (*c*) typical vaccinia restores a completely lost immunity.

If poor virus has been used, the results are unreliable. (*a*) Failure proves nothing; (*b*) vaccinoid gives only partial immunity; (*c*) vaccinia will probably not be observed. If it is, it con-

fers immunity, and shows that the operator happened to encounter a good streak in a lot of poor virus.

Vaccine Virus.—The Necessity of Having It Tested Physiologically Before It is Issued, and of Retesting It Frequently.

I shall say nothing about the form in which vaccine virus should be issued. I believe, however, that glycerinated virus is the best. I do wish to emphasize very strongly that all virus should be subjected to a rigid physiological test, preferably upon previously unvaccinated children, before it is issued. This is the only way in which its efficiency can be positively established. One would think that, in all vaccine laboratories, such tests would be made as a matter of course, but I believe that much of the commercial virus is not thus tested. Either its efficiency is inferred from the appearance of the eruption upon the calf which furnishes it, or at most, each lot is tested by inoculation in one or two spots upon the next animal to be vaccinated. This, I believe is not sufficient.

The virus with which I have had most experience is tested as follows: it is inserted in three spots upon each of five previously unvaccinated children, and must result in 15 vesicles of good quality and size in order to reach the standard required for issuance. It must take not merely in every *case,* but in every *spot* in which it is inserted.

If virus is to be kept for any length of time it should be retested every month, as it has been found that some virus, though up to the standard at the time of issue, is unaccountably short-lived. The duration of efficiency of glycerinated virus is fairly constantly proportionate to the degree of dilution. A great deal of the commercial virus is far too dilute to retain its efficiency long. That which is issued by the vaccine laboratory of the New York City Health Department is diluted in the proportion of one part by weight of pulp to 3, 4 or 5 by bulk of a glycerin and water mixture, consisting of two-thirds glycerin and one-third water; the usual ratio of pulp to glycerin and water is 1 to 3. The average duration of continuous efficiency in the virus collected in 1896 and 1897 from 117 consecutive animals, as shown by frequent retests upon children was 7.7 months.

Methods of Vaccination.

It has already been shown that four spot vaccination confers the most complete immunity.

Site of Scarification.—In the female subject, the scarification may well be made, for cosmetic reasons, upon the leg instead of the arm. The only objection to this site is that in babies and young children a pock in this situation is more difficult to keep clean. In older persons, it is rather more likely to be sore than when it is situated upon the arm, because the leg cannot be kept so constantly at rest; but these objections are trivial when compared with the misfortune of having to carry through life an unsightly scar upon a member which is so often displayed in society.

The lower and outer part of the thigh is often selected as the site of scarification. If a spot in this region gets very sore, it is difficult to keep a dressing over it, especially in the adult subject. The upper and inner aspect of the leg is sometimes chosen. In this position a very sore pock might interfere somewhat with bending of the knee, and there is possible danger of thrombosis of the adjacent internal saphenous vein.

The best site is probably the anterior-external aspect of the leg, over the uppermost part of the tibialis anticus muscle. A pustule in this position is far enough forward not to be pressed upon when the person lies on the side; it is near no large vein, it does not interfere with bending of the knee, and if it gets very sore a dressing can be easily retained over it. In the male subject, the skin of the upper arm over the insertion of the deltoid is the site of election.

Methods of Scarification.—Many methods have been employed. They may be classified as follows: (1) Puncture, with lancet or hypodermic needle; (2) linear incision, with lancet or needle; (3)scarification of an area by means of lancet or needle; (4) denudation of an area by means of a solution of caustic potash.

Any one of these methods may be used, though I think two of them are open to some objections, namely, (*a*) the hypodermic method. It is difficult to inject merely into the skin. The needle will almost inevitably go though into the subcutaneous tissue; and Chauveau has shown that by this means a generalized vaccinal eruption may be produced; (*b*) denudation of the skin by means of a solution of caustic potash. This is the least painful of all methods of scarification. Great skill is, however, required to avoid denuding too large an area. Moreover, the action of the caustic causes the formation over the denuded area of a parchment-like eschar. This eschar is composed of necrosed tissue killed by the action of the caustic, and, as I have shown in a series of experimental cases, it materially interferes with the absorption of the virus; so that vaccination by this method is likely to be uncertain in its results.

The simplest and best method I believe to be the scarification of *small* areas with a needle. Virus as active as that now being issued by the Health Department of this city will result in pocks of unnecessarily large size if the scarified areas be more than one-eighth inch square.

As to the technic of the operation, a few longitudinal scratches well into the deep skin, are sufficient It is not necessary to scarify crisscross. For cosmetic reasons it is well to try to draw as little blood as possible, but it is a mistake to think that any ordinary blood-flow will interfere with the success of the vaccination, if the virus is thoroughly applied.

Outfit for Vaccination.—A convenient vaccinating outfit is one such as is issued by the New

York City Health Department. It consists of a needle, an hermetically sealed capillary tube containing glycerinated virus, a bit of rubber tubing of caliber corresponding to that of the capillary tube, an orange-wood toothpick with one broad end.

Directions for Vaccination.—(1) Wash the region to be scarified, with alcohol, and let it dry by evaporation. No other cleansing is necessary. (2) Wash the needle point with alcohol, or hold it for a moment in the flame of an alcohol lamp or gas jet, then make a few longitudinal scratches which shall penetrate well into the true skin, over an area not more than one-eighth inch square. The number of spots thus scarified should correspond to the number of vesicles which it is desired to produce. The spots should be at least one inch apart. It is a matter of indifference except for the sake of appearances, whether blood is drawn or not. (3) Break off both ends of the capillary tube, insert one end in the rubber tube, and blow out the drop of virus upon the broad end of the toothpick. (4) Apply the virus to the scarified areas, and scratch it in thoroughly with the sharp corner of the toothpick. It is not sufficient merely to smear the virus on. (5) Leave the limb uncovered for a few minutes until it has at least partially dried.

After-care.—The best dressing is a very loose sleeve (or stocking), lined with clean linen or with absorbent gauze. The use of shields is of questionable value. Those which tie on are an abomination. If tied tightly enough to stay in place, the arm is uncomfortably constricted; if tied more loosely they slip, and the vesicles are very likely to be destroyed by the hard edge of the shield. Those shields which fasten on by means of adhesive plaster are often left in place too long, the pustules become macerated, and running sores are the result.

A word as to the care of sore arms. In my opinion, an infected and discharging vaccination wound should be cared for, or at least kept under observation by the physician. Many a mother who would not dare attempt to deal with any other infected wound, struggles on bravely, but ignorantly, trying to care for an infected pock, because, forsooth, "it is only a vaccination sore." This mistaken attitude, assumed by the mother, and usually approved of, or at least not objected to, by the physician, is, I believe, responsible for more than half the putrid sloughs and slow-healing ulcers which are so often seen.

There is a very general belief, even among physicians, that the pock, though infected, should not be opened, for fear of impairing the protection afforded by the vaccination. It is, of course, well to avoid breaking the vesicle of a normal uncomplicated vaccination, but remember that destruction of the vesicle does not impair the immunity, and do not hesitate in an infected case to remove the scab, open the pustule, clean the base thoroughly, and treat the wound upon general surgical principles. Much unnecessary suffering may thus be avoided.

Points to be Emphasized.

1. Complete natural immunity to vaccination is practically unknown.

2. In primary cases, delayed vesiculation, raspberry excrescence, and abortive course, mean poor virus.

3. Among the complications, there is now no danger of transmitting syphilis or tuberculosis. Other infections such as erysipelas, cellulitis, septicemia, etc., are more rare as methods of preparing virus improve, and more care is used at the time of vaccination and in the subsequent management of the case.

4. During the second week of vaccinia, a large painful areola may be considered normal if it be bright red, and if the vesicle be of typical appearance. If the vesicle be irregular, filled with greenish pus, and the areola be of a dark livid, purplish hue, the case is one of mixed infection.

5. Generalized vaccinia, aside from cases in which the eruption is spread by auto-inoculation, is rare. Cases of doubtful diagnosis may be tested by the inoculation of lymph from one of the vesicles into another subject. If it be true generalized vaccinia, a localized vaccinia will develop in the inoculated person.

6. The destruction of the vaccine vesicle does not interfere with the immunity conferred by the vaccination.

7. Immunity is acquired about the time the areola is at its height—eight to ten days after vaccination. If smallpox appears at this time it will be mild. If the eruption appears before the vaccination has reached the areolar stage, the disease will not be much modified by the vaccination.

8. Vaccination of the pregnant woman does not protect her child.

9. The fetus *in utero* may have smallpox, if the mother has it, and may be born with an active rash or with healed scars. A child born while the mother has smallpox is not only not protected, but has been exposed *in utero*, and will probably develop the disease before there is time to secure protection by vaccination.

10. The duration of immunity to smallpox which is conferred by vaccination is extremely variable, and in the presence of an epidemic, the fact of recent successful vaccination is only presumptive evidence of immunity. Of persons successfully vaccinated within five years, very few will contract the disease; but some will, though they will probably have varioloid instead of severe smallpox.

11. The duration of immunity to revaccination which is conferred by vaccination is also extremely variable, and is probably short (two years or under) in a larger proportion of cases than has been supposed.

12. The protective power of vaccination is in direct proportion to its excellence and completeness as shown by the number and quality of the resulting scars. Of the two elements which enter into this protective value, quality of scars is more important than number.

13. While the quality of a scar is a fair indicator of its protective power against smallpox, it is an untrustworthy guide in deciding whether the individual is susceptible to revaccination.

14. A person who is immune to smallpox can often be successfully revaccinated.

15. Revaccination protects against smallpox as fully as an attack of the disease protects against a subsequent attack.

16. A person who has been successfully revaccinated is much less likely to contract or to die of smallpox than a person who has been vaccinated only once. The more successful vaccinations one has had at different times, the more certain is his immunity, and the better his chance of recovery if he does contract the disease.

17. Revaccination, therefore, should be considered as important as primary vaccination, and should be just as systematically practised.

18. Primary vaccination should be performed in infancy, revaccination at school age. In the presence of an epidemic, however, revaccination should be performed even though the primary vaccination was of comparatively recent date.

19. The eruption in revaccination is more likely to follow the type of vaccinoid, than that of typical vaccinia.

20. Vaccinoid protects if the virus used is of high-grade efficiency. If the virus is poor, only partial immunity is conferred.

21. All vaccine virus should be subjected to rigid physiological tests before issuance. It should be retested monthly, so long as it is on sale. The virus from each animal should be kept by itself and numbered. It should be known by this number when issued so that it can be called in if retests show that its efficiency has expired.

22. Vaccination should be performed under aseptic precautions.

23. It is not sufficient merely to smear the virus upon the scarified areas. It must be thoroughly rubbed or scratched or pricked in.

24. Vaccination shields often do more harm than good.

25. Cases of infected vaccination should be cared for by the physician and not by the mother.

26. Remember that the destruction of the vesicle does not impair the protective power of vaccination, and if signs of mixed infection appear, open the vesicle, cleanse the wound and treat it upon general surgical principles.

THE METHOD OF PREPARATION OF VACCINE VIRUS IN THE VACCINE LABORATORY OF THE NEW YORK CITY HEALTH DEPARTMENT.

BY J. H. HUDDLESTON, M.D.,
OF NEW YORK.

The vaccine virus at present used by the Health Department is entirely animal. It will doubtless be remembered that Galbiati began the use of bovine virus in 1803 in Naples, and that his successor, Negri, introduced the practice in Paris in 1864; that in 1870 animal vaccination was brought to this country, and that in 1876 it was adopted as the uniform practice of the Health Department of this City.

The reasons for the preference of animal virus to human virus are that with the former, first there is less possibility of the communication of disease, especially of syphilis, and, second, it is not necessary to open, or in any way mutilate the vesicles on the arms of children, and, therefore, there is less possibility of a late infection occurring in them.

The animals used are calves. While goats, sheep, pigs, and several other animals are susceptible to vaccinia, and can furnish in an emergency a virus which will produce the typical disease in the human body, they are all inferior to calves and cows in the amount of virus, or the typical character of the vesicles produced, or in the ease with which they can be handled. With reference to the choice between calves and older animals of the same species, decision rests on the fact that the calves have a softer skin and the vaccine vesicles on them run a more typical course. The calves are chosen for their health and good quality of the skin; this means that they receive a careful examination before vaccination. After vaccination they are killed and their organs are examined for possible disease. If disease is found at their entrance into the laboratory, they are not vaccinated. If disease is found at autopsy the virus obtained from them is rejected.

The diseases that are considered of practical consequence are tuberculosis and skin disease, for although it has never been demonstrated that tuberculosis has been conveyed by vaccination it is easy to avoid the suspicion that it may be. There have been reported from abroad some cases of skin disease which were thought to have been inoculated with virus coming from calves having skin disease. For safety's sake, therefore, only healthy calves are chosen.

The calves are females so that the urine being discharged behind the animal the stall may be kept clean. After the animal is cleaned, and that means that the skin is curried, brushed and washed, and that the hoofs are scrubbed, the animal is placed on a bench, on its side, with one hind leg fastened in a vertical position, and the skin over the posterior abdomen and on the inside of the thighs is shaved. This particular part of the skin is chosen because it is found by experi-

ment that in no other part of the body are the vesicles so large and so typical.

The animal is then taken to a separate operating-room, which, it may be said in passing, has a cement floor, glazed brick walls, and the same operating furniture that is found in a hospital operating-room. Here the calf is covered with towels except that portion of the skin on which vaccination is to be made, and this portion is washed with soap and water and with alcohol. This is, of course, not a notably antiseptic preparation. It has been found that treating the skin so as to make it as nearly as possible aseptic, for it cannot be made by any means entirely aseptic, simply roughens the skin and makes dirt adhere to it more firmly during the week in which the part must be largely unprotected.

On this clean skin is then made a series of superficial incisions, about one quarter of an inch apart, and covering the entire shaven area. Linear incisions are preferred to scarifications because with the former more typical vesicles result and a larger amount of virus is secured; they are preferable to punctures because the former yield more virus. The incisions in some cases draw blood enough to show a red line, in other cases they do not show red at all; they are made superficial because deep incisions are found to be more apt to become infected, and because they cause more pain to the animal. Into these incisions the seed virus is rubbed. This seed virus is either humanized virus collected by touching sterile pieces of bone to the serum exuding from ruptured vesicles on the arms of children, or, in the great majority of cases, bovine glycerinated virus, which has been preserved two months or longer. It has been found that fresh bovine virus when used as seed produces some sort of infection of the animal with consequent degeneration of the virus, whereas old virus is free from that objection.

No cover is placed over the vaccinated area, for although covers have been contrived, and although there has been much experimenting done in this direction in Germany, as well as in this country, nothing has been found which will stay in place satisfactorily, and in those exceptional cases in which a cover does maintain its place it is not found that the virus is any more free from extraneous substances than when the only cover is the natural crust.

The animals are well cared for and fed on milk, their temperature and general condition is watched closely, and usually on the sixth day after vaccination, sometimes on the fifth, rarely on the fourth, and rarely on the seventh, the virus is collected. For this purpose the calf is again placed on the table in the operating-room. The vaccinated area is cleaned and the vesicles, which have formed, are scraped from their beds with a sharp curette. This pulp is weighed and emulsified by running it through a mill on which a mixture of 66 per cent. of glycerine and 33 per cent. of water flows. This proportion is chosen because pure glycerine has an antiseptic effect on the vaccine organism, while diluted glycerin does not injure the virus, but kills only the extraneous germs. The proportion of virus to glycerine and water is usually one to three. It is sometimes one to four, and sometimes one to five. Sometimes the pulp is found to be rather watery, and in that case less glycerine and water is necessary. Sometimes it is rather solid, and then more can be added. Proportions as small as one-to-ten or one-to-fifteen have still been found efficient, but as a rather dilute virus cannot be considered as certain in its action as a more concentrated one it has been thought wise to keep the percentage of virus in the emulsion high.

This emulsion is drawn into large glass storage tubes, which are sealed at each end by flame, and is preserved in these until needed for use. It is then poured from the tubes into vials, which are used when many persons are to be vaccinated at one time, or poured into small receptacles from which capillary tubes are filled, when the vaccine is to be used for one person at a time.

Every lot of virus issued bears stamped on it the number of the calf from which it was taken, and the date of collection. Before issue it is tested as to its efficiency by use on five previously unvaccinated children, and after issue watch over its efficiency is maintained by retests made at more or less regular intervals.

It is always found that the fresh virus and the fresh emulsion contain large number of saprophytes. It is impossible by any means to get fresh virus without these organisms, but the great majority of them die out in the glycerine emulsion in the course of a few weeks. Some persistent ones may last one or two, or even three or four months, but they are non-pathogenic.

MEDICAL PROGRESS.

Treatment of Pneumonia.—With the exception of typhoid fever, few subjects in therapy have caused so much discussion as the treatment of pneumonia for while a suitable antitoxin is still lacking, all measures must naturally be empirical or symptomatic. H. Passler (*Münch. med. Woch.*, Feb. 19-26, 1901) warns urgently against falling into any routine plan of treatment and by pointing out the various way in which a pneumonia may kill indicates how Nature may be supported. Death may ensue (1) by direct asphyxiation, the surface of lung remaining uninvolved being too small to lead to proper oxygenation of the blood. Such cases are, however, rare; (2) through failure of the right heart on account of the increased resistance offered to the pulmonic circulation. This occurs less frequently than is generally supposed for high-graded dyspnea and cyanosis with edemas and increased cardiac dulness, which would naturally follow, are not often observed before death and the danger to life stands by no

means in direct relation to the amount of lung-tissue implicated; (3) complications frequently settle the fate of the patient. The most important of them are chronic alcoholism, cardiac disease and advanced age. But all these factors are subservient in importance to the last; (4) the developing of a pneumococcus sepsis with a resulting paralysis of the vasomotor centers. It is this cause which so often proves fatal to young and healthy individuals who at first seem to have the best chances for recovery. The first principle in treatment should be to prevent the spreading of the inflammation. Local applications to the chest in the form of moist packs, ice-bags, cupping or mustard plasters, by diminishing the pain, will do much to accomplish this end since the respirations are rendered more effective and stagnation of infectious matter is prevented. Should such methods be insufficient it is proper to give small doses of morphine which also act as expectorants. High temperatures require lukewarm or cold baths, but a clouded sensorium is a still greater indication for them. The surest way of relieving overfilling of the right heart is venesection. Alcoholics require whiskey in sufficient amount to sustain them and bromides with opium rather than chloral, which always depresses the vasomotor center, may be in place. With the onset of the first symptoms of cardiac insufficiency the free use of digitalis or digitalin becomes absolutely necessary and in all cardiac cases the dietetic treatment plays an important part. But few remedies stand at our disposal when sepsis appears, it is then merely possible to stimulate the circulatory system with strychnine, digitalis, salt infusion, and last, but not least, caffeine, which has an especial tonic action on the vasomotor center.

Suprarenal in Hemoptysis.—The necessity for a prompt and reliable remedy, free from toxic or unpleasant after-effects, to control hemoptysis has led W. B. Kenworthy (*Med. Rec.*, Mch. 16, 1901) to try suprarenal extract. In fourteen cases the hemorrhage stopped quickly, and in only one case did it continue beyond fifteen minutes after the first dose. There was also decided strengthening and slowing of the pulse, lessening of cough and expectoration, and marked improvement in respiration. The writer gives powders of gm. 0.2 (gr.iij.) every half-hour until three are taken; then every two hours until three more are taken; then three times a day for a week. He orders them taken dry on the tongue, chewed, and swallowed without water.

Staining of Plasmodia.—G. Maurer (*Münch. med. Woch.*, Feb. 26, 1901) recommends the following modification of the Romanowsky stain for plasmodia. A one-per-cent. aqueous solution of medicinal methylene blue with one-half of one-fourth-per-cent. of soda is allowed to stand for from two to three weeks at 37°C. or for from four to eight days at 60°C. Then a one-tenth-per-cent. aqueous, yellowish, water-soluble solution of eosin is prepared; 15 drops of the first solution are then added to 25 c.c. of water, 15 drops of the second to another 25 c.c. of water; both dilutions are then poured together and the slide immersed for from thirty to forty-five minutes. The red cells will appear pink; the platelets, dark carmine; the nuclei of the leucocytes, dark red and their body red; the nuclei of the lymphocytes, dark red, their body blue with red granules, while the malarial bodies appear blue with red centers. With the tertian parasite peculiar red dots appear in the erythrocytes with this stain.

Typhoid Fever.—Of 137 cases treated at the Royal Victoria Hospital in Montreal, and reported by D. B. Gillies (*Montreal Med. Jour.*, Feb., 1901) the average age was twenty-four years, ranging from two and one-half to sixty-one. The largest number of cases was admitted during June, the smallest during March. The most frequent symptoms at onset were anorexia, general malaise, and frontal headache. One case began like pneumonia; in 12.4 per cent. a rigor occurred at onset or in the first week; 25 per cent. began with diarrhea; 26 per cent. with vomiting; 13 per cent. had delirium; one case acute mania, and 24 per cent. had epistaxis. The "rose spots" were present in 69 per cent.; in 2 cases there was diffuse erythema; in 4 cases a purpuric rash, and in one a rash of macules, papules, and petechiæ. The spleen was palpable in 61 per cent. and earliest felt on the fourth day. There were 5.4 per cent. of relapses. In one case the maximum temperature was 100° F. Perforation occurred in 4 cases, jaundice in 2, cholecystitis in one, meteorism in 20 per cent., and intestinal hemorrhage in 12 per cent., in four of which it was fatal. Systolic murmurs were heard in 11 cases; acute dilatation of the heart occurred in two, femoral phlebitis in five on the left and two on the right side and brachial phlebitis in one case. The lung complications were acute bronchitis in 18 per cent.; dry pleurisy, pleurisy with effusion, tuberculosis, and acute lobar pneumonia. There was hematuria in 2 cases, febrile albuminuria in 10 per cent., acute nephritis in 3 cases, suppurative otitis media in 4, abscesses in 6, periostitis in 3, arthritis in one, superficial gangrene in 2, and tender toes in 10 cases. The Widal reaction was negative in only one case, but was not recorded in 4 cases. It appears earliest on the fourth day, and latest on the thirty-third day. On the day of discharge the reaction was present in all but 6 of 96 patients. Ehrlich's reaction was found in only 34 per cent.

Prophylaxis by Antitoxin.—P. R. Blake (*Lancet*, Jan. 26, 1901) reports absolute prevention in 35 patients. In 31 patients no reaction followed injection; in no patient did any local lesion occur at site of injection. In the 4 patients in

which reaction occurred no severe symptoms developed; the highest temperature was 101 F., the rash, eruption lymphadenitis and arthritis appearing only to vanish in a few days.

Arsenic in Spleno-Medullary Leucemia.—Charles Heaton (*Lancet*, Jan. 26, 1901) cites an unusual case of tolerance to this drug when injected hypodermatically and with a weak solution of Eucaine B. The patient had been taking liquor arsenicalis in very small doses; m ij-iij by mouth, t. i. d., but gastric irritation prevented its continuance. The total number of days of treatment was 271, including intervals amounting to 58 days, and the total amount of hypodermatic administration was: Arsenious acid, 5½ grains; arseniate of soda, 105 grains. The maximum dose was 2⅔ grains of arseniate of soda, equivalent to 4 drams 26 minims of liquor sodæ arseniatii. Twenty minims of a 1:500 solution of Eucaine B., in which the arsenic salt was dissolved, together with the use of a very fine needle did away with any pain which might otherwise have accompanied the treatment. It is interesting, however, to note that despite the use of these heroic doses there was no paramount improvement, this case seeming to show that arsenic is, at best, no more than palliative in this obstinate blood discrasia.

Caustics and Cancer.—J. Courtin (*La Gynecologie*, Feb. 1, 1901) aside from the surgical extirpation of the cancerous uterus reviews the methods and usefulness of caustics as therapeutic measures. They have the advantage of being within the reach of those whose surgical experience is limited and of coming into the field when operation has failed or can not be done, but the disadvantage of almost always provoking violent and incontrollable spread of the disease if used on early nodules. It is therefore best to use cauterization and its adjuvants curetting and partial extirpation only when the disease is so extensive as to defy total removal. The actual red-hot iron is a more efficacious instrument than the electric or the Paquelin cautery for such duty as this. Chemical caustics are either injected into the cancer substance or in the form of pencils embedded in it. Chiefly used in this way are the acids, acetic, sulphuric, hydrochloric, nitric, chromic and phenic. All have the advantage of compelling frequent dressings which are in themselves of service. Bromine from 1 in 16 to 1 in 5 parts in solution is occasionally employed, that which escapes into the vagina must be neutralized there by bicarbonate of soda. Arsenious acid, grm. 0.20; cocaine, grm. 1.00 and water to 100.00 grams is in the writer's experience a most valuable formula for injecting. A judicious use of caustics will keep an inoperable cancer clean, odorless and as near a healthy granulating surface as its nature can permit.

Tuberculosis.—C. F. Martin and F. T. Tooke (*Montreal Med. Jour.*, Feb., 1901) find many cases of tuberculosis which give few or no outward signs of disease. There is a type with slight persistent hacking cough and little or no expectoration; also the type in which a large hemorrhage is the first sign, and cases in which chronic bronchitis and emphysema mask the signs. Some cases begin as acute bronchitis and others give a long history of repeated "bad colds." Some have been treated for anemia, others for neurasthenia, and many for gastric disease. Pains in the stomach and diarrhea were most common in these masked cases. Fistula *in ano* is always suspicious. Certain cases with marked involvement and symptoms have no fever; and some with proper food and rest may gain from week to week even with marked daily fever.

THERAPEUTIC HINTS.

Atropine in Hyperchlorhydria.—Antonio Storet, after a series of investigations, concludes that atropine, whether given by mouth or hypodermically, produces as its first effect a constant and characteristic diminution in the gastric juice. However, after several days its power is lost, and the hyperchlorhydria is as bad as ever. At the same time certain disagreeable sensations of motor activity of the stomach supervene. The dose used was gm. 0.0005 (gr. $^1/_{150}$) given half an hour before the meal.

Vomiting After Anesthesia.—During the first 6 to 12 hours give one to two teaspoonfuls of toast-water or hot water, writes Hunter Robb (*Cleveland Med. Gaz.*, Feb., 1901) and keep the head on a level with body. For persistent nausea give 2 or 3 tablespoonfuls of hot water with gram 0.7 (gr. x) of sodium bicarbonate. Repeat every hour when necessary and apply mustard to epigastrium. Lavage may be of advantage in some cases, and treatment for constipation or tympany is always indicated. As a last resort a hypodermic or morphine over the epigastrium may relieve the extreme retching. The persistence of vomiting for 3 or 4 days after operation is very suggestive of peritonitis.

Epilepsy.—Toulouse recommends the administration of sodium bromide and at the same time reducing to a minimum the sodium chloride ingested. Bunge states that 1 or 2 grams (gr. 15-30) a day of the latter will suffice for an average man, though many ingest as much as 20 or 30 grams (℥v-viii). If this surplus salt is replaced by sodium bromide the life processes continue normal, and in 20 of Toulouse's cases the aggregate diminution in the attacks amounted to 92 per cent. He advises the following diet. 7 a.m., milk, 250 c.c. (℥viii); 11 a.m., coffee and two cakes made with eggs, farina, milk, and sugar; 3 p.m., porridge mode with farina, sugar, boiling milk, etc.; 5.30 p.m., bouillon unsalted, boiled beef unsalted, potatoes, fresh beans or peas, fruit in moderation. He gives grams 2.0 (gr. xxx) of sodium bromide daily.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 30, 1901.

THE BELLEVUE HOSPITAL REPORT.

We publish in full this week the report of the Medical Board of Bellevue Hospital, which has been the subject of so much discussion. The abuses that have been hinted at, the reforms that have been suggested, the radical change of methods that are needed are herein succinctly set forth.

We by no means underestimate the value of the improvements that have taken place as a result of Commissioner Keller's investigations, and we fully appreciate the fact that Bellevue's palmiest days never touched anything like the present standard of perfection. Yet we are mindful of the fact that this report is an accurate statement of conditions that existed a few months ago, and we are also aware that Commissioner Keller's term has not many more months to run. When his energy and coöperation are removed will this upward tendency degenerate down to the conditions on which this report is based? We have seen too many reformers, who, like

"The King of France with forty thousand men
Marched up the hill and then marched down again,"

and we fear that unless the reform is assured the hospital will retrograde and sink into the hands of the politicians who at present have discretion enough to "lay low and keep on sayin' nuffin'."

The work of the Charter Revision Committee is slowly being rounded out and we trust that the trustee system which is there advocated may soon be put in operation in this, one of the city's grandest possibilities.

THE SEMICIRCULAR CANALS.

Motor troubles consequent to lesions of the semicircular canals of the ear have formed the groundwork of a series of hypotheses relative to the functions of these organs. Many of these hypotheses are characterized by their extreme ingenuity, yet it cannot be said that this question of physiology has been thoroughly made clear. The fundamental questions seem to be, are the troubles which follow section and destruction of the semicircular canals due to their absence, to the paralysis of any organ, or are they to be classed as reflex phenomena, determined by some form of mechanical irritation?

An ingenious method of experimentation has been recently utilized by G. Gaglio of the Pharmacological Institute of Messina (*Archives Italiennes de Biologie*, Vol. 31, p. 377). By the use of cocaine thrown directly into the semicircular canals, he believes that he can thus bring about a temporary abolition of their function and in this manner can determine, in part at least, what that function is.

Experiments first made on pigeons, by sectioning the various canals and then applying cocaine, demonstrated that the application of the cocaine did not markedly modify the motor disturbances which were induced by sectioning and further research brought out clearly that the action of the cocaine induced a set of symptoms similar to that produced by the destruction of the organs in question. The pigeons were unable to fly, staggered, and made incessant oscillatory movements of the head lasting for about one-half hour, coincident with the stage of anesthesia produced by the cocaine; the ability to fly was the last power regained. Vomiting or attempts at vomiting were noted.

From these experiments and many others, the author comes to the conclusion that it is idle at the present time to formulate hypotheses concerning the function of the semicircular canals. Many more facts are needed.

One fact, however, seems fairly well established by these experiments by means of cocaine. They seem to prove that the peculiar motor symptoms characteristic of section or destruction of these canals are due to the suppression of a definite function and are not reflex acts induced by sensory or traumatic irritation.

A SOCIETY FOR THE STUDY OF PRACTICAL HYGIENE.

The reports of the officers at the annual meeting of the "Society for Instruction in First Aid to the Injured," on Friday, February 15, 1901, showed such a magnitude of work accomplished that the founders of that society must be exceedingly gratified.

Many lives have undoubtedly been saved, and an immeasurable amount of suffering avoided by the services of graduates of those classes. The knowledge of what to do in emergency cases, until a doctor arrives, is often the means of keeping intact the thread upon which a life hangs. Furthermore, the greater intelligence regarding the treatment necessary for various surgical conditions has rendered the laity much more ready to submit to a rational procedure than they often times were before the origin of this society. Is the time not now ripe for the formation of a Society for Instruction in Practical Hygiene? The stopping of a hemorrhage or the resuscitation from asphyxia by artificial respiration is most dramatic and the results are the more gratifying because so evident, but nevertheless the intelligent prevention of disease by a knowledge of the manner of communication is fully as important and could be made of use every day by every member of the society. The wide dissemination of an understanding of the practical laws of hygiene would be of more weight with legislative bodies toward the enactment and fulfilment of sanitary laws than any amount of political maneuvering. Six or eight lectures would give a class a correct and working idea of the general principles of preventive medicine. Physiology, therapeutics and materia medica would all need some attention. The idea being, not to teach how to diagnose or how to prescribe drugs, but rather to explain the difficulties encountered by the physician; that what the patient often considers the disease is but a symptom and that the dose for one man may be double what another man needs, or not the right drug at all, even though they are both suffering from the same malady. Bacteriology would be given a great deal of attention and the diseases caused by a known micro-organism could be studied more in detail. The various processes of sterilization, and the practical ways of preventing the spread of tuberculosis and typhoid fever, would, of course, be of great value to every one.

MARRIAGE, INSANITY AND THE LAW.

The law-makers of the State of Minnesota are contemplating a step to check insanity by making it illegal to marry without a physician's certificate as to the saneness of mind of the contracting parties, and the soundness of intellect of both their families. At first sight it seems somewhat difficult to legislate for such an end, for here the physician must certify that no brother or sister, father or mother or even grandfather or grandmother, was afflicted with chronic imbecility or insanity; and the minister who marries two people without such a certificate showing a sound condition of mental health in both families is liable to a fine of $1,000, or not more than five years' imprisonment.

Whether or not the bill, if passed, will fit all cases, or whether it will force a large number who have afflicted relatives to take a wedding trip to another State for the marriage ceremony, is not the issue. There are so many exceptions of congenital or accidental insanity, of epilepsy not due to hereditary causes—in fact, good authorities ascribe the affection in nearly 70 per cent. of the cases to trauma during birth—and of imbecility that has no connection with the family history, that the law would undoubtedly strike many whose marriage might be perfectly safe.

The real issue is, will such a law tend to decrease in the coming years the increasing number of those who are now flocking to the insane asylums of the State? Senator Chilton who introduced the bill and many of the physicians of the State who are strongly in favor of its passage, urge that it will be of undoubted benefit, as so many of the children that become public charges are the offspring of parents who were, either or both, tainted with insanity or imbecility.

The fact that the thoughtful consideration of *mental health* which physicians have so often, but vainly, urged, has become a sentiment so widely spread as to enable a bill to pass the Senate of the State is at least a sign of a popular awakening to a realization of the

horrible statistics of the slow but sure results of such indiscriminate marriages.

If there were any way of shortening the effect of time and presenting human experience to individuals in a rapid series of vivid consecutive pictures of cause and effect, the people would be the first to cry out for laws to protect them. No one questions the laws that prevent leprous, cholera and plague patients from entering our communities and mingling with the people, because the fatal consequences follow so quickly that the people learn their object lesson with revolting horror. But could they see in as many days, as it takes years, the development of insanity, the slow, pitiful suffering of the unfortunates and the horror and anxiety and heart-break of their friends in the cases that spring, with the fatal regularity of statistics, in the children and grandchildren and great-grandchildren of a person who has insanity in his family, if these could be presented to the people as vividly as the physician sees them, there could be no more telling object lesson, and one would as readily share his marriage-bed with a leper or a plague-patient as with a person directly tainted with insanity.

Although the law may bungle, and the neighboring States may help people to evade it, yet it is sentiment in the right direction, for if the problem of heredity could be cut out of insanity half of the existing asylums might be turned into "fresh-air" resorts.

ECHOES AND NEWS.

NEW YORK.

Roosevelt Hospital.—It is reported that Dr. Walter B. James has been appointed as Visiting Physician to Roosevelt Hospital to succeed Dr. Francis Delafield.

Anti-Hypnotism Bill.—The bill of Mr. Babcock aimed at the practice of hypnotism, mesmerism, suggestive therapeutics, and allied phenomena was the subject of a hearing before the Assembly Public Health Committee on Wednesday.

Reception to Dr. Dana.—The Medical Club of Philadelphia gave a reception to Dr. Charles L. Dana of this city Friday night, March 29th.

Secretary of Health Bureau.—Dr. Daniel Lewis, of New York, State Commissioner of Health, has appointed Dr. William E. Johnson, of Waverly, Tioga county, formerly State Senator, as Secretary of the Bureau of Health. The salary is $2,500 a year.

West Side Burglars.—Those burglars noted in the Medical News of last week entered the house of Dr. Brill this week and stole some valuable jewelry.

New York Academy of Medicine.—At a stated meeting of the Academy on April 4th, the order will be as follows:— Subject: "The Duty of the Public to the Medical Profession." Paper by D. B. St. John Roosa, M.D., LL.D.; paper by W. H. Thomson, M.D., LL.D.; discussion by Drs. A. H. Smith, F. R. Sturgis, A. Jacobi, F. P. Kinnicutt, and others.

The American Laryngological, Rhinological and Otological Society.—Owing to an oversight the dates selected for the Annual Meeting of the American Laryngological, Rhinological and Otological Society are the same as those of the American Climatological Society. The American Climatological Society is to meet in Buffalo, and, owing to the crowded condition of Buffalo during the Exposition, it would be difficult for them to change their date. It has therefore been decided to hold the Annual Meeting at the New York Academy of Medicine in the City of New York on May 23, 24 and 25, 1901.

Certificate for Pure Milk.—The Milk Commission of the Medical Society of the County of New York had a meeting last week at the Academy of Medicine. About forty milk dealers were there. The commission agrees to guarantee or certify the milk of all dealers desiring such certificate. The standard required will be that the acidity must not be higher than .2 per cent. and that the milk must not contain more than 30,000 germs, or bacteria of any kind, to the cubic centimeter. The butter fat must reach 3.5 per cent. Labels will be supplied to dealers who pay for the cost of inspection.

PHILADELPHIA.

Epidemic of Pinkeye Threatened.—A number of cases of this disease have lately appeared and it is apparently increasing in prevalence, one practitioner having seen six cases in one forenoon. The city has not had a severe epidemic of this disease for several years.

Hospitals to Receive Little State Aid.—The chairman of the State Legislative Appropriation Committee has stated that the appropriations for hospitals this session will be cut down because of the heavy expenses connected with the new State Capitol at Harrisburg. In addition to the charge against the West Penn. Hospital in Pittsburg, noted in this column recently, a number of Grand Army men have filed a complaint that Grand Army members are turned away from the institution though there is a fund supposed to be expressly for their care at this hospital. Charity patients have also made complaints. Inquiry may terminate in a formal investigation.

Dr. Wyeth to Speak in Philadelphia.—The guest of honor at the Academy of Surgery April 1st will be Dr. John A. Wyeth of New York, who

will read a paper on "Amputation at the Hip-Joint for Sarcoma; the Tendency to Recurrence."

Pennsylvania Hospital Officials Answer Mandamus.—The authorities of the Pennsylvania Hospital in answer to the demands of the court in the case of Miss Mariane H. Wood, the nurse who seeks reinstatement, state that they are not legally bound to reinstate Miss Wood, because she was an employee, subject to discharge at the discretion of the officials. The hospital was incorporated solely for the purpose of caring for the sick and insane and the training school for nurses is not a "third department" of it. They deny that Miss Wood has had no hearing nor opportunity for hearing and also refute her claim of a conspiracy against her.

Forceps as Rotators.—At a recent meeting of the County Medical Society Dr. Richard C. Norris spoke on the management of cases of arrested posterior position of the vertex. In the hands of the general obstetric practitioner podalic version is the best working rule. In cases where forceps are necessary Dr. Norris has for the past three years been using them as rotators with gratifying success. No extensive lacerations of the soft parts are caused and the child is exposed to no greater danger than by other procedures. The Tucker solid blade instrument is used for this purpose.

Partial Hysterectomy for Necrosis of the Uterus.—Dr. Barton Cooke Hirst reports two cases of recovery from streptococcic puerpural infection and necrosis of the uterus which he believes were due to the character of the operation employed. Only the softened, necrotic area of the uterus was removed instead of doing a total hysterectomy as formerly. The procedure is offered as being more quickly and easily done and productive of less shock to the patient.

Neurological Society.—At the meeting of March 25th Dr. F. X. Dercum exhibited an interesting case of epiphysitis with hysterical joint manifestations added. The patient was a man of thirty-seven years who has had pain in the left shoulder since he was ten years of age. The upper half of the left arm is more than two inches shorter than the right. This is the third case of epiphysitis with arrested development coming under the notice of Dr. Dercum, one of the others following an attack of scarlet fever.

Dr. William C. Pickett read a report of observations concerning the scapulo-humeral reflex of Von Bechtern. Studies were made on 122 cases of hemiplegia, tabes, etc. In 40 cases the reflex was not obtained. Dr. Pickett found that adduction and external rotation which are Von Bechterew's typical signs were not so common as were abduction and slight flexion of the elbow. The presence of the reflex is considered significant, but its absence is of uncertain value.

CHICAGO.

Vaccination Decision.—Judge Dunne has decided that school authorities have no right to exclude from the schools children who have not been vaccinated, unless an emergency which necessitates guarding from smallpox is shown to exist.

Chicago Medical Society.—At a meeting, held March 20th, the subject for discussion was neurasthenia. Dr. L. Harrison Mettler read a paper on the pathology of neurasthenia in which he took the ground that this, like all the so-called neuroses or functional diseases of the nervous system, has a pathology because function and structure are so intimate and interdependent that disturbance of the former presupposes alteration of the latter. The pathology of neurasthenia is confused, even in its conception, by the uncertainty surrounding the meaning of the word neurasthenia. Nerve exhaustion, if secondary, is often only the manifestation of deleterious influences, both inside and outside of the body, upon a sympathetic and highly responsive nervous organism. Such a neurasthenia will, of course, include in its pathological findings many extra-neural alterations, such as anemia, hyperemia, enteroptosis, auto-intoxication, gastro-intestinal catarrh, blood changes, phosphaturia, oxaluria, and almost every known pathological condition, local and general, familiar to medicine. Therefore, in true primary neurasthenia the pathology must be sought in the molecular or chemical conditions of the nerve elements or neurons. Little that is certain is known about these intraneural changes. As to the pathology of the congenital form of neurasthenia, one can say absolutely nothing. There is a pathology, therefore, of nervous exhaustion, but knowledge of it, at the present time, is only a matter of inference, founded upon experimental research.

Etiology of Neurasthenia.—Sanger Brown stated that refinements in business methods, with the development of devices providing means of constant intercommunication, expose the business man to incessant drafts upon his capital of nervous energy; while keenness of competition, the added responsibility of success, as well as the anxiety and depression incident to failure, all contribute to nerve bankruptcy. Indeed, in this connection the excessive indulgence in venery, sometimes practised by the overworked business or professional man, might consistently be termed neurogenic defalcation, or in lesser degree peculation. But if the increasing complexities of modern civilization offer a menace to the neurons of business and professional men which may fairly excite concern, what shall be said of their effect upon the neurons of the modern society woman, with her perpetual breakfasts, luncheons, receptions and card parties; her clubs with their educational, municipal and philanthropical departments? And even under the weight of these great burdens, yielding to primitive impulses, she may attempt to divert some energy to the family circle, as, for instance, personal supervision of the housekeeping, the training and education of her children, etc. In her efforts to meet all these demands, besides many others, her liability to

neurasthenia is positively alarming, and accordingly sooner or later she is likely to register at a rest cure. Some of the severest cases of neurasthenia develop rather rapidly after an emotional or physical shock, and when these causes act coincidentally, their influence is powerfully intensified. The symptoms supervene sometimes within a few hours, sometimes within a few days or weeks of the exciting cause. He has repeatedly seen undoubted cases of severe and protracted neurasthenia result from these causes alone or combined, when there could be no possible motive for deception. Now and then cases are met with in which well-marked symptoms have developed independent of any exciting cause—cases which, in the present state of knowledge, may properly be termed idiopathic. As to predisposing causes, age may be first considered. The active period of adult life furnishes a large majority of the purer cases, mainly because at this time the individual exposure to exciting causes is at its height. There is a large and perhaps increasing proportion of individuals in every civilized country, mainly among the middle and upper classes, in none of whose organs actual disease can be demonstrated. They are not insane nor yet imbecile; but they lack endurance and stamina to such an extent that they are always more or less dependent on some one, no matter what educational and hygienic advantages may have been extended to them. The condition is permanent. It may have been present from birth, in which event it might properly be regarded as congenital or hereditary; or it may have resulted from some severe disease occurring during the period of development.

Treatment of Neurasthenia.—Dr. Archibald Church read this paper. In practice male and female neurasthenics must be treated differently, although their cases may be comparatively similar. In a case of marked neurasthenia in a woman the rest cure may be undertaken with a fair prospect of its resulting favorably. The keynote in the rest cure is isolation. It is important to place the patient in an entirely different atmosphere and under different surroundings. Isolation means exclusion of the friends from the patient, the cutting off of visits, and in some cases the cutting off of correspondence with the patient. A second essential in the rest cure and management of neurasthenia and hysteria, especially neurasthenia, is to establish an atmosphere of constant hopefulness.

GENERAL.

American Laryngological Association.—The Twenty-third Annual Congress of the Association will be held at New Haven, Conn., Monday, Tuesday and Wednesday, May 27-29, 1901. The President of the Congress is Dr. Henry L. Swain of New Haven.

Discovery of Supposed New Ether.—Dr. John A. Cooke, professor of chemistry in Morningside College, of Sioux City, Ia., is said to have announced the discovery of a new kind of ether, which chemists to whom it has been submitted declare will prove of greater practical value than that ordinarily used. Its specific gravity is lower and its color is orange yellow. It has been found very effective in surgery.

Medical Society of City Hospital Alumni, St. Louis.—At the last regular meeting of this society, held March 21, 1901, the following papers were read: Dr. L. H. Behrens—A Case of Gall-Stone Impaction Simulating Appendicitis; Dr. A. E. Taussig—A Case of Duodenal Stenosis due to Gall-Stones; Dr. R. F. Amyx—(1) A Modification of the Liston Splint with Method of Application, (2) Presentation of Hospital Patients; Dr. F. R. Fry—Types of Migraine.

Quarantine Rules Modified.—In view of improved conditions in Cuba, and the fact that passengers as well as vessels are inspected before leaving Cuban ports by the United States quarantine officers, and suspected baggage disinfected, the Treasury Department has so modified existing regulations as to permit, until April 15, 1901, travel from Cuba of non-immunes after their inspection at port of departure and necessary disinfection of effects. This waiver includes the northern ports.

To Regulate Marriages.—The State Senate of Minnesota on March 23d, passed Senator Chilton's bill prohibiting the marriage of insane, epileptic, and idiotic persons, and requiring a medical certificate of all applicants for marriage licenses. Amendments were adopted making the physician's certificate not quite so sweeping, and permitting the marriage of any feeble-minded person over forty-five; the bill originally having extended such permission only to women. The bill passed by a vote of 34 to 17.

Tuberculosis in Texas Jails.—It is not generally known that Texas has isolated its consumptive convicts, thus keeping in the front rank of modern ideas regarding the treatment of this malady. Not only this, but these ailing convicts receive treatment practically similar to that followed in sanitaria for consumptives. Their diet is of a highly nourishing character, and includes stimulants. Cleanliness in quarters and the observance of sanitary precautions are imperative. When able to leave their beds, the men are required to be in the open air, and they sleep in a spacious stockade, where each enjoys as much breathing space as he would in a forest camp. No one is required to work beyond his strength, and employment is entirely in market-gardening. Yet this isolated convict farm has returned to the State in two years a net profit of about $2,500. Thus far the results of this mode of living and treatment have been of the most gratifying character. Many men who went to the farm apparently in the last stages of consumption, and who were scarcely able to feed themselves, are now hearty and stout, evincing not the slightest objective evidence of consumption, and the death rate from this disease is steadily diminishing. A

like segregation of consumptive convicts was ordered recently by the Alabama Legislature.

Lepers in the Philippines.—According to the reports of the Marine Hospital Service leprosy is widely prevalent over the entire archipelago, but the greatest number of cases exists in Southern Luzon and the southern islands. It is quite prevalent in Cebu, the number of lepers being estimated at 2,000. The total number of cases in the islands is estimated at 20,000, but the actual number is not known, and a census is difficult on account of the majority of cases being in the rural districts. The cases in Manila and surrounding country are isolated in a substantial hospital under the auspices of the Manila Board of Health. There is also a leper hospital at Cebu. An attempt at segregation and isolation of the lepers in the islands has been made by the army officials, and several months ago orders were issued from headquarters directing that a hospital in each district be set aside for the isolation of the lepers that could be apprehended, and a Board of Army Officers was detailed recently to investigate several islands for the purpose of selecting a suitable one for a leper colony, the intention being to deport all cases of leprosy to this place for segregation and isolation.

Tuberculosis Congress.—American medical scientists will be both numerous and prominent at the World's Tuberculosis Congress, to be held in London during the last week in July. Professor William Osler, of Johns Hopkins University, has been invited by the management of the Congress to organize the American contingent. Among those who have already signified their intention of coming are Dr. Trudeau, of New York; Professor Solly, of Colorado; Dr. Herman Biggs, of New York; Professor McEachran, of Quebec.

Dr. J. G. Adami, professor of pathology at McGill University, has been appointed Vice-President of the section of pathology and bacteriology of the International Congress on Tuberculosis to be held in London in July under the patronage of King Edward. Dr. Adami will attend.

Professor Koch, of Berlin, and Dr. Brouardel, of Paris, have announced their intention of actively participating. Dr. Malcolm Morris, of London, the originator and secretary general of the Congress, is reported as saying: "Certainly tuberculosis never called together so distinguished a body of international experts. Delegates will attend from probably every civilized country of the world. From the United States, it goes without saying, we expect the keenest kind of men and ideas. We have decided to establish a temporary museum, illustrative of the treatment and prevention of tuberculosis in both men and animals."

An International Sanitary Treaty.—Two South American States, Argentina and Uruguay, have agreed upon a treaty of sanitary protection, relating generally to contagious and infectious diseases, and especially to the bubonic plague. The provisions of this treaty are broad and liberal, and while guarding against undue interference with commerce, tend to the protection of both States in a very sensible and practical way. Among other things, it provides that if the plague, or any other infectious disease capable of being transmitted by sea, shall make its appearance in either country, ships clearing for the other shall be inspected and thoroughly disinfected, including the baggage of passengers if from places where the existence of the disease is known or suspected, to the end that they may sail with a clean bill of health. The treaty does not provide that the quarantine on either side shall be lax, or that any proper precautions shall be neglected, but arranges for mutual good offices for joint protection against the preventable transmission from one country to the other of diseases which may become epidemic.

American Association of Pathologists and Bacteriologists.—The first annual meeting of this association will take place next week, April 5th and 6th, at Boston. From the program issued the meeting promises to be unusually attractive. The Introductory Address will be delivered by Dr. W. T. Councilman of Boston. Some of the papers to be read are as follows: Pathology of Spleno-lymph Glands, by A. S. Warthin, Ann Arbor; Multiple Leiomyoma of the Kidney by J. H. Larkin, New York; Transplantation of Tumors by Leo Leob, Chicago; Hodgkin's Disease by C. F. Martin, Montreal; Biology of Pest Bacillus by E. H. Wilson, Brooklyn; New Formation Nerve Cells in Cerebral Tumor by W. L. Worcester, Danvers; Trichinosis by H. V. Williams, Buffalo; Growth of Bacteria on Serum Agar by E. Libmann, New York; Suppurative Pyelophlebitis by Charles Norris, New York; Sudden Death in Epilepsy by A. P. Ohlmacher, Gallipolis; Cholecystitis and Typhoid by J. H. Pratt, Boston; Liver Necroses by F. B. Mallory, Boston; Porencephaly by D. A. Shires, Montreal; Proteolytic Enzymes and Chemical Studies by E. R. Baldwin, Saranac Lake and P. A. Levene, New York; Variation in Virulence of Human Tubercle Bacilli by A. J. Lartigau, New York; Primary Endothelioma of Lung by Isaac Adler, New York; Genital Noma by George Blumer, Albany; Streptococcus Mucosus by W. T. Howard, Jr., Cleveland; Bacteriolysis and Typhoid Immunity by W. M. Richardson, Boston; Cerebrospinal Meningitis and Bacillus Pyocyaneus by R. G. Perkins, Cleveland; Bacillus Diphtheriæ by F. P. Gorman, Providence; Intestinal Bacteria by W. W. Ford, Montreal and Cholesteatomata of the Brain by J. J. Thomas, Boston.

As to Quackery.—The excellent editorial comment on this subject by the New York *Sun*, should not go by unnoticed. It shows a just appreciation of the problems involved.

"It is a curious characteristic of human nature, or of a great deal of human nature, that people who grudge paying a cent to a regular medical practitioner will cheerfully pay a great

deal of money to an irregular medical practitioner. Go where you will and you will find the quack prosperous. His rooms are full of patients and his patients are full of faith. Men and women will buy wondrous remedies from traveling mountebanks who do not disdain to sing a comic song on the wagon from which they peddle their nostrums. Natural bone-setters, and long-haired "Indian doctors," and botanic doctors ignorant of botany, and faith healers of many kinds, abound; and the trade of most of them is good. The world likes to be healthy, but it loves to be humbugged.

"If a thousandth part of the blind, unhesitating faith that cleaves so readily to incompetent and often illiterate practitioners of fantastic means of healing were bestowed upon religion there would be no complaints that the churches are not filled. But often those who are full enough of doubts of the supernatural so far as it relates to their souls are quick to believe in an almost or altogether supernatural gift of quack-salves to cure the body.

"Legislation can do but little, if anything, to interfere with the gains of the medical pretenders or of the professors of visionary and semi-religious medical 'science.' You can not legislate away a state of mind; and the state of mind of thousands, perhaps millions of persons, is one of crass credulity in humbug. Their delusions and illusions can be removed only by experience and a wider knowledge. They take their own lives and the lives of their families in their hands when they neglect the methods and the agents of modern medicine and surgery and resort to the moonshine of Christian Science or to any other crank system or to any individual quack. But you cannot prevent people from killing themselves if they have the will; and you will only stimulate faith in quackery by giving it a chance to yell 'Persecution!' A private arrangement between patient and 'healer' will nullify any provision of law forbidding the 'healer' to heal for a consideration. A gift can take the place of a fee; and 'gratuitous' treatment can be acknowledged with a gratuity.

"The best way to deal with a delusion is to let it alone. Common sense must win in the end."

A National Consumptive Sanitarium.—An official announcement, indorsed by all the Denver papers, was issued March 23d regarding the establishment of a sanitarium for consumptives. It says: "To save the lives of thousands of persons belonging to other States from death from tuberculosis is the object of an organization of Denver physicians and other professional men and women for the establishment and maintenance of the Rocky Mountain Industrial Sanitarium, which has just been incorporated here. The organization aims to be national in scope and has the indorsement and support of many of the foremost physicians of the United States. The institution is not for profit. No dividends can be declared and the net earnings will be used for the improvement and betterment of the enterprise. Its purpose is to aid the great majority of tuberculosis patients in poor or moderate circumstances who come to Colorado and other mountain States in the hope that the climate and altitude alone will aid in effecting a cure, and who, almost invariably, either from lack of means or proper direction, are immediately surrounded by conditions which preclude improvement or recovery.

The plan provides for the erection of a sanitarium about twenty miles from Denver, to be conducted as an industrial colony. A large amount of money will be required. This, it is expected, can be raised by the 'cottage endowment plan.' To secure these endowments by individuals, fraternities, clubs, societies, churches, colleges, alumni, labor unions, etc., the Young Woman's Sanitarium Auxiliary has been organized. A branch of the auxiliary will be established in every city and town in the United States. By utilizing the labor of patients it is expected that nearly all the work of the institution will be performed, the entire sanitarium supplied with provisions and a great variety of remunerative industries carried on. The industrial nature of the institution will enable patients to avail themselves of a change of climate while the disease is in its incipiency and before they are incapacitated for light, open-air employment."

A Tuberculosis Conference at Ottawa.—According to the Marine Hospital reports, the prevalence of consumption throughout the Dominion of Canada has become so great as to cause alarm among all classes of people. Less than two months ago, in response to public demand as expressed through the press, Governor-General Earl, of Minto, called a public conference to meet in Ottawa on February 14th to consider what means should be taken in order to overcome the ravages of tuberculosis. Invitations to this conference were issued by the governor-general to representative people all over Canada—ministers, physicians, lawyers, and statesmen. When the conference assembled there were found to be present over 500 participants. It was formally opened in an address by the governor-general, and Sir James Grant was made the permanent presiding officer. In the governor-general's address it was stated that the death rate from consumption was steadily growing, and in the Province of Ontario alone, between 1867 and 1898, had amounted to no less than 32,000. Although statistics are not available, the death rate from consumption in the Province of Quebec is even greater than in Ontario. The annual estimate of deaths from consumption for the whole Dominion is placed at between 7,000 and 8,000. According to Sir James Grant's statement, tuberculosis carries off

more than 5,000,000 of the human race annually.

The conference continued in session three days, and the discussions were most interesting from beginning to close. Dr. Fraser, of Brandon, representing the Indian department of the Federal Government, spoke of the awful prevalence of tuberculosis among the Indians. From his own observation he affirmed that 95 per cent. of the sickness among the aborigines was tuberculosis in some form or another, and worse still, the fatalities were practically 100 per cent. of those affected. In fact, the race was dying out in consequence.

Resolutions were adopted demanding that the Government take measures to prevent the entrance into the Dominion of tuberculized immigrants and tuberculized cattle.

An association was organized, the official name being "The Canadian Association for the Prevention of Tuberculosis." The objects are stated to be, generally, to combat and prevent tuberculosis in the Dominion of Canada. Specifically: (1) To enlighten and educate the public in regard to the disease and the principles of prevention and cure. (2) To influence legislatures to do all within their power to assist in means of prevention and cure. (3) To encourage the erection of sanatoria within reach of the people, and the passing and enforcing of adequate sanitary laws. (4) To take means to arouse sufficient interest until governments, municipalities, and people are brought into such systematic cooperation as to make full provision for the whole of the people.

The above purposes to be accomplished by (1) The establishment of a central office for the preparation and distribution of suitable literature and for correspondence. (2) The institution of public lectures. (3) Articles in the press. (4) Periodical congresses and an annual report. (5) Appealing to every province and territory to inaugurate local associations to carry the work into every municipality. (6) Appealing to life insurance companies, benefit societies, etc., to make proper protection to non-tuberculous insured.

Obituary.—Dr. George Wren, the house physician at St. Vincent's Hospital, New York, died there last week of typhoid fever. He was born in Bridgeport twenty-seven years ago. He was a graduate of Fordham College and in 1899 was graduated from the Bellevue Medical College, going at once to St. Vincent's Hospital. He was appointed house physician in January. His father, Peter W. Wren, is President of the Board of Health in Bridgeport.

Dr. William Francis Channing, noted scientist and son of the philosopher, Dr. William Ellery Channing, and cousin of the late Rev. William Henry Channing, once Chaplain of the United States Senate, died at the Perry Hospital March 20th. Dr. Channing was born in Boston and was graduated from Harvard in 1839, being a classmate of Dr. Edward Everett Hale. He later took a course in medicine at the University of Pennsylvania, receiving his diploma in 1844, but never practised.

Dr. Richard K. Valentine, fifty years old, committed suicide last week at his home, 190 Lincoln place, Brooklyn, by cutting his throat with a lancet. About a week ago he was prostrated by a severe attack of the grip. He was under the care of several physicians and two trained nurses. He became delirious last night, and the nurses were constantly at his bedside, but in spite of them he managed to kill himself.

Dr. John Henry Hobart Burge died last week at his home, 132 Montague street, Brooklyn, of heart disease. He was born at Wickford, R. I., in 1823. His father was the Rev. Lemuel Burge, who was pastor of the Narragansett Church. Dr. Burge was graduated from the College of Physicians and Surgeons in this city. The following year, 1849, as surgeon on the bark "Ann Welch" he made a trip around Cape Horn to the gold fields of California. While in San Francisco he founded the first hospital there. He returned to Brooklyn in 1851 and had practised medicine there ever since. He was consulting physician at the Long Island College Hospital and St. John's Hospital. He was a charter member of the Practitioners' Club.

Dr. Mary F. West, one of the oldest women physicians in this city, and a graduate of the Woman's Medical College of the New York Infirmary, died suddenly at her home, No. 122 East Twenty-eighth street, last week. Dr. West, who was sixty-one years old, had practised in this city for more than twenty years.

Dr. S. Edgar Mortimore of New York City died on the operating-table at the Church Hospital in Orlando March 22d. Dr. Mortimore was born in New York in 1850. He attended the public schools and was graduated from the Eclectic Medical College in 1871. He was afterward Professor of Anatomy in that college and a practising physician in Harlem for thirty years.

Dr. Ralph J. Hess, twenty-seven years old, died this week in the scarlet-fever hospital on North Brother Island. Dr. Hess joined the Bellevue Hospital staff on June 1st last. He was taken sick last Monday night and no alarm was felt until the following day when he developed symptoms of scarlet fever. He was then removed to the Willard Parker Hospital, but owing to the crowded condition of that hospital he was removed to North Brother, where he died.

EMERGENCY HOSPITAL AT THE PAN-AMERICAN EXPOSITION.

An attractive and useful feature of the Buffalo Exposition will be the emergency hospital, which is illustrated here. It is to stand at the west end of the Mall. In conformity to the general architectural scheme of the Exposition build-

ings, the free Spanish Renaissance type of treatment has been followed.

It is to have a frontage of about 90 feet on the Mall; and in the main is but one story high, but it covers a considerable ground floor space. Modern arrangements that are both convenient and sanitary mark every feature. Approved medical and surgical appliances have been most carefully selected especially for their adaptability to emergency work and the exigencies that are likely to arise. The first floor front contains in the extreme western wing, two male wards with seven cots each, a bathroom, physicians' office, a morgue and a linen-chest. The eastern wing contains a woman's ward, large enough to hold a dozen cots, with direct communication to the woman's bathroom. Dr. Roswell Park is the Director; Dr. Vertner Kenerson, Deputy Director, and Dr. Alexander Allen is the resident physician.

In regard to the importance of this adjunct to the Exposition it may be said that up to March 1st five hundred and four cases have been treated on the grounds, only one of which proved fatal. These include all forms of sickness and accidents to workmen employed upon the construction work. In this connection it is well to note that the number of cases treated at the Omaha Exposition was about three thousand, while the history of the hospital at the World's Fair in Chicago gives a total of 11,602 medical and surgical cases treated, resulting in 69 deaths.

It is hoped to have less use than this for the hospital at the Pan-American, though in the immense crowds which will attend, no doubt, many individuals will have occasion to appreciate the provision that has been made in this direction.

Plague's Ravages in India.—The Calcutta correspondent of the *Daily Mail* says: "Eight thousand people died of the plague last week in Bengal alone, including Calcutta. Whole towns are being deserted."

Bell Bill Withdrawn.—Dr. Nelson Henry has withdrawn the much modified and discussed Bell Bill. It was found to be impossible to please all the various interested parties and it is understood that a new bill is contemplated.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 16, 1901.

"THE DUMMY CORPSE"—THE OUTBREAK OF SMALLPOX IN GLASGOW—THE HOSPITALS COMMISSION—THE HOUSING OF THE POOR IN LONDON—INCREASE OF ALCOHOLIC LUNATICS IN SCOTLAND IN CONSEQUENCE OF THE PROSPERITY OF THE COUNTRY—THE NEW SYDENHAM SOCIETY—DECLINE OF MEMBERSHIP—PROPOSED ATLAS OF DIAGNOSIS IN MEDICINE, SURGERY AND OBSTETRICS.

Mr. Marsh, the practitioner who was in attendance in the "dummy corpse case," which I have already described in a previous letter, has contributed to the *Lancet* a complete account of this extraordinary fraud. I need now only summarize the additional points narrated by the doctor. The patient was a man, aged thirty-five, who called at the doctor's office on January 14th complaining of difficulty of micturition. Mr. Marsh prescribed for him and did not see him again until the 25th. On the 29th the doctor was summoned and found him in bed in a very weak state, with a temperature of 103°. He complained of severe pains in the loins and constant headache and said that his feet and legs swelled when he was out of bed and that for some time he had been frequently passing small quantities of porter-colored urine. He remained in bed for the following eight days during which the doctor visited him regularly and obtained samples of his urine daily. It was acid, specific gravity 1026, and always contained considerable quantities of albumin. On one occasion the reaction for blood was obtained and there were numerous hyaline and some granular tube casts. On February 4th the albumin had largely increased and the patient was very collapsed, deadly pale almost pulseless, and suffering from a severe rigor. He said he would send for his brother and wrote a letter to him which the landlady posted. On Feb-

ruary 5th he appeared to be very drowsy and showed convulsive movements of the limbs. Fearing uremia the doctor tooks measures accordingly and saw the patient at night again. Though free perspiration had been induced the drowsiness continued and with difficulty could a reply be elicited. Next morning a man much resembling the patient called on the doctor stating that "his brother" had died at 4 A.M. in a fit and gave a description of a uremic convulsion. He wished "the body" to be removed lest it should be an inconvenience in the house. Later in the day the doctor visited the house and found "the dummy corpse" described in my previous letter. On being arrested the patient confessed that he added albumin to his urine, but said that he had been very ill. For obtaining a death certificate by false pretences he was sentenced to nine-months' imprisonment.

The official report shows that in Glasgow during the past week 130 fresh cases of smallpox were admitted to hospital, of which 90 were dismissed cured and 10 deaths occurred. The number of deaths since the beginning is 134 and the greatest number of cases in hospital at any one time was 456, on February 8th.

In reply to a question in the House of Lords, Lord Raglan, Under Secretary for War, said that the report of the Hospitals Commission was very important and lengthy and that the Government had hardly time to digest the suggestions, but they were fully alive to the importance of thorough reorganization of the Army medical system, and that they would avail themselves of advice from the heads of the profession or other sources.

The housing of the poor has now become a burning question in London. The working man, unless he lives miles from his work, must pay an exorbitant rent for one room in a small house inhabited by two or three other families. The poorest class pay a high rent for a single room out of a starvation wage. From earnings of six, eight, or nine shillings a week gained chiefly by women who form the huge army of boxmakers, artificial flower makers, belt and umbrella makers, paper-bags, etc., as much as three or four shillings are paid for a single room. The London County Council has in hand 37 schemes for the erection of artisans dwellings of which several represent the abolition of insanitary areas. It has provided accommodations for 32,000 persons and is committed to build dwellings for 12,000 more. It is well known that the King takes a great interest in this subject. When Prince of Wales he presided at a Commission which investigated the problem of the housing of the poor.

At the annual meeting of the Royal Edinburgh Asylum for the Insane, the largest establishment of its kind in Scotland, Dr. Clouston the superintendent said that the admissions to the asylum for the past year constituted a record and that the excessive use of alcohol during a period of brisk trade and high wages had to a large extent been the cause of an undue amount of mental disease. His alcoholic lunatics had risen from an average of 15½ per cent. in 1874-88 to 24½ per cent. in 1900. All this apparently resulted from the prosperity of the country. Yet the politicians said they could do nothing. The author is convinced that some day they would have a big reckoning. A consumptive race might conceivably be cured in two generations, but a drink-sodden race could not be cured in 100 years.

The New Sydenham Society which is now in its forty-third year is in financial difficulties. It was founded with the object of publishing translations of most important medical works which appeared in foreign languages and has done excellent service, giving for an annual subscription of five dollars usually about three volumes. In its palmy days its list of members was as high as 3,000; it is now only 1,400. Mr. Jonathan Hutchinson who has been Honorable Secretary since the foundation explains that this decline is due to perfectly natural causes. The condition of medical journalism and of the publishing trade has declined in the Society's lifetime. The supply of medical literature is now very liberal and works of real merit published abroad do not now wait long for translation. The Society cannot possibly compete with private enterprise in promptitude. In brief the *raison d'être* of the Society has to a large extent been removed. Of late the Council has had increasing difficulty in finding works for translation which should fulfil the two needful conditions of being at once of great permanent value and likely to be acceptable to a wide circle of readers. Works such as those of Trousseau, Hebra, Charcot and Hirsch are no longer available. There are plenty of valuable monographs on special subjects, but they would interest only a few. The question of winding up the affairs of the Society has therefore been under consideration; but before doing so it has been determined to endeavor to publish an "Atlas of Pictorial Illustration of All Subjects Relating to Diagnosis in Medicine, Surgery and Obstetrics. It is calculated that if 2,000 subscribers could be obtained 4 or 5 fasciculi of from 8 to 10 plates each could be produced annually and that the work could be completed in five years.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

ENTERECTOMY — PYONEPHROSIS — FIBROMATA — SCARLATINA.

A. G. Barker, at the Royal Medical and Chirurgical Society, February 26, 1901, reported two cases of enterectomy to show the limita-

tions of this operation. The first patient was a woman, fifty-eight years old; multiparous; glycosuric to six per cent. of sugar; afflicted for nine months with indefinite abdominal discomfort increasing to decided pain and obstinate constipation; admitted to the University College Hospital, October 3, 1900. At that time she showed a tender tumor above and to the left of the umbilicus, fist-size, movable, little affected by distending the stomach, but displaced into the right iliac fossa by filling the colon with air, and therefore indicating colonic obstruction, probably cancerous with more or less intussusception. Her generally favorable condition warranted an operation, at which five inches of the colon were removed, October 25th. She showed an excellent reaction from the operation, a temperature of about 100° F. for the first nine days, assimilated rectal food for the first four and small quantities of fluid from the second day onward by the mouth, she bore morphine, three to four times daily for three days, and then phosphate of codeine, in grain-doses hypodermatically thrice daily, combative of her glycosuria, which at this time had reached its maximum, 6.6 per cent. This condition speedily disappeared altogether under the drug and diet. Once she surreptitiously ate sugar and grapes and next day showed 2.8 per cent. of sugar, but again recovered from it. Her recovery from the operation was steady and, except for some sloughing of the mesentery, uneventful. Very evidently there are glycosurics who repaid well operative damage. The second case was a robust woman, seventy-six years old, with a strangulated ventral hernia through an ovariotomy scar since 1870; no children; multiple large fibroids of the uterus; admitted January 10, 1901, to the hospital with the classical symptoms of strangulation persisting during the 8th and 9th. Upon exposing the hernia, a pint of intensely fetid, fishy fluid gushed out, three feet of the small intestine herniated through the omentum showed little luster, no cracks of the serous, punctate ecchymoses, subserous thrombosis, distention and practical gangrene. Five and one-half feet were resected, end-to-end anastomosis with the Murphy button was quickly done. From beginning to end the procedure occupied sixty-three minutes. Normal salt solution was slowly injected subcutaneously during the operation. Recovery was perfect. It seems that these resections show that some bear them well and that in children a compensatory hypertrophy of the remaining small intestine occurs to account for the large loss they sometimes bear.

F. W. Pavy in the discussion said that operations upon diabetics of the alimentary type succeed, but fail in the combined type. In the former, diet corrects the disease; in the latter, noxious matters like acetone and diacetic acid as well as sugar are in the blood.

T. Smith recorded a case of a man not previously known to be diabetic, who after scratching his finger promptly died of septicemia and gangrene of all four extremities of a malignant, rapid type.

A. Doran, at the Medical Society of London, February 25, 1901, reported a case of painless, feverless pyonephrosis, treated successfully by nephrectomy. The woman was thirty-eight years old, mother of eight children, always healthy up to a year ago; soon after marriage was attacked by a purulent vaginitis contracted from her husband who had strictures and cystitis. Her last child was born five years and a half ago. The history reported a mass in the right side causing discomfort when her corsets were on, but without sensation when undressed; denied hematuria, renal colic, fever and chills. There was albumin in the urine occasionally. There was a large movable kidney in the right side. Through a Langenbeck incision, the kidney was easily removed. A complete and prompt recovery followed. The organ was cystic, purulent and calculous. Evidently the gonococcus in ascending infection was at the bottom of this trouble.

A. H. N. Lewers read a monograph on fibromata of the cervix. These occur much less frequently than do those of the body of the uterus, usually solitary, occasionally multiple, present as subserous, interstitional, submucous or polypoid varieties. When their size is considerable they always displace the fundus upward which may be palpated as a mass on the top of the tumor at the neighborhood of the umbilicus. Under such conditions of size the neighboring viscera always give symptoms, the rectum constipation, the bladder frequency of urination, the ureters compression. The uretus is variously affected. Menorrhagia is the rule, but amenorrhea for long periods of time may occur. The author then presented four specimens of these tumors, which tended to demonstrate his points. The first uterus had a large anterior solitary interstitial fibroid which had made the patient profoundly anemic through menorrhagia. The next organ had a single large posterior tumor, which caused at times painful urination, at times involuntary flowing of it, almost total amenorrhea as the woman had menstruated only twice in two years. In these intraperitoneal hysterectomy *per abdominem* was signally successful. The third patient underwent abdominal hysterectomy for the removal of a nine-pound-eight-ounce subserous fibroid which had stripped off the serosa from the recto-uterine and left iliac fossa and intervening walls of the pelvis, obliterating the peritoneal cavity in this region and displacing the sigmoid colon to the right side from the level of the umbilicus downward. A stump of the cervix was also left in this as in the other two cases and recovery followed. The fourth

womb showed a large sinistro-posterior subsero-interstitial fibroid, with a left ovarian cyst all successfully treated by panhysterectomy. The diagnosis of these tumors rests upon a patent os exterium and a palpable intracanicular tumor. A careful distinction between these and submucous fibroids of the body must be made, because the latter can be removed by pieces, but in the cervix this is disastrous.

A. Newsholme, at the Epidemiological Society of London, February 15, 1901, discussed scarlatina, its epidemiological relation, especially as regards the influence of isolation upon it. That a specific organism not yet isolated with absolute scientific accuracy is the cause of this disease is certain; because it is killed by heat and other powerful disinfectants and is transmitted by personal contact and intercourse, by fomites and such media as milk. Until the life history of this germ is discovered and described our duty remains to combat it by isolating diseased patients and by disinfecting and destroying contaminated materials. One feature already established is the cyclical recurrence of periods of maximum and minimum prevalence and mortality. These vary from year to year, but do not correspond year for year in one town compared with others.

In England from the years 1859 to 1883 the mortality had never been less than 0.28, except in 1873, following excessive mortality in 1872, it was 0.19, in 1884, 0.36, and has since reached 0.08 per 1,000 as the minimum. This improvement was partly, but not wholly ascribable to the use of isolation hospitals, because in towns where no such institutions existed, a similar improvement had been seen in certain years. The very low mortality in such places immediately after periods of great or excessive death-rate could be explained on the basis of exhaustion of all susceptible material. It is peculiar that when such respites from scarlet fever occur, there is almost always an outbreak of bad diphtheritis. This has occurred so frequently as to suggest, but not yet consistently enough to prove a correlation between these two diseases. To assume that the present slight prevalence is due entirely to the isolation process would be erroneous, although it has secured better conditions in towns of good sanitary conditions over those of equally good conditions, but without isolation hospitals. Isolation in most houses is not possible, therefore the hospital is justifiable. An attenuation of the virus is the other factor now at work to determine the low fatality, just as early in 1900 it existed and led one observer to conclude that the depletion treatment was the cause. A recurrence of the virulent type corrected his opinion. Nevertheless isolation is a safeguard, and should be adopted by all advanced and civilized communities.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting, Held February 14, 1901.

William L. Stowell, M.D., Chairman.

Vomitus Nervosus.—Dr. Louis Fischer presented a girl of thirteen whom he has had under observation for six years, and in whom attacks of nervous vomiting have occurred as often as five or six times a week during that period. The first quest in the case is naturally as to whether it is a case of ulcer of the stomach. But all the pathognomonic symptoms of ulcer are lacking. The pain, or rather discomfort, that precedes the vomit is not acute, but rather an uncomfortable feeling. The tenderness is not localized at one point, but is over the whole stomach. Digestion seems to be considerably interfered with and the food is often but slightly changed when it is returned. Though there are practically no stigmata of general hysteria, Dr. Fischer is inclined to think that this vomiting is nervous in origin and has a hysterical condition for its basis.

Dr. Einhorn said that the condition is evidently not due to ulcer of the stomach since the pain is not localized at a particular point, but is felt all over the epigastrium. The periodic recurrence of the paroxysmal vomiting points to an underlying nervous condition.

Hyperesthesia of the Stomach.—Dr. Einhorn said that a marked hyperesthesia of the stomach mucous membrane is sometimes a stigma of hysteria. It corresponds with the occurrence of hyperesthetic patches in the skin. Usually this hyperesthesia is associated with some disturbance of the gastric secretions.

Where hyperchlorhydria exists pain occurs not immediately after eating, but later in the course of digestion. The treatment of the condition requires above all that the child shall be encouraged to keep back the vomiting as much as possible and her general system properly toned up. On days during which paroxysms are to be expected ferments should be administered. Between the paroxysms tonic stimulants are indicated.

In concluding the discussion Dr. Fischer said that there is a general tendency to hyperesthesia all over the child's body and the gastric hyperesthesia seems only a part of this. The stomach contents have frequently been examined and were usually found to be normal. Occasionally an excess of hydrochloric acid was found. The most successful treatment consisted in the administration of nerve sedatives, such as the bromides and morphine.

Infantile Diabetes.—Dr. William E. Young

reported a case of diabetes in a child under one year of age. When the child came under examination the specific gravity of the urine was 1,030 and it contained 5 per cent. of sugar Moreover, the infant was passing about double the normal amount of urine. A certain amount of albumin and some casts were found in the urine, though the nephritis seemed only to be due to irritation on account of the amount of sugar passed. On palpation the liver was found to be considerably enlarged and the kidneys seemed to be about four times their normal size. When the case came under observation the physical signs of diabetes had existed only for about a month. The child was very markedly marasmic. Its skin was dry and it suffered from thirst. Death took place in about four weeks. Codeine was administered very freely, but seemed to have no effect either on the amount of urine passed or on the amount of sugar. At the autopsy marked hyperemia of the kidneys was found and these organs were more than double their normal size. Unfortunately the kidneys were inadvertently thrown away..

Origin of Infantile Diabetes.—In these cases there is usually a history of diabetes in the family. Pavy has noticed the influence of this even as far as the third generation. No family history of diabetes existed in this case. At times during scarlatinal nephritis, glycosuria occurs. The same thing is true of whooping-cough even when it is not complicated by nephritis. Careful study has shown in considerably more than half the cases of whooping-cough that there is some sugar in the urine. It is probable that some infectious agent may be the cause of the rapidly-fatal diabetes that occurs in children.

In the discussion Dr. Fischer said that he has recently had under observation two children of respectively eight and six years, who suffered from glycoruria for several months after an attack of pneumonia. This fact is to be borne in mind when examinations are being made for life insurance, for, shortly after recovery from one of the infectious fevers, patients may be refused who would be otherwise good risks.

Dr. Stowell said that he had seen the case reported by Dr. Young and that its marked features were the drying up of the patient, the enlarged kidneys and liver. It seems unfortunate that microscopic examination of these organs was not obtained, as some light might have been thrown on the origin of infantile diabetes.

Milk Modification Apparatus.—Dr. Charles Hermann presented a simple apparatus for the modification of cow's milk for baby-feeding. Any milk-modifying apparatus should present three requirements. First, it should not be expensive; second, it should not be too complicated; and, third, it should admit of easy changes of formula. In this apparatus advantage is taken of the fact, demonstrated by Dr. Holt, that the cream rising to the top of the milk furnishes a ready standard for the determination of the amount of fat that a milk may contain. Dr. Hermann's apparatus consists of a graduated cylinder mounted on a stand and with a stopcock at the bottom. The cylinder is graduated from the bottom up so as to show the amount of milk that is still in the cylinder and not how much has run out. The milk is allowed to stand in it for some hours until the cream has risen. It is then drawn off. A very simple calculation enables one to decide just what is the proportion of fats and proteid material in the milk. The apparatus may also be used in determining the quality of a milk. The instrument being graduated to 1,000 c.c. the proportion of cream can be read off directly. Besides this a comparison of the specific gravity of the whole milk and of the under milk shows the richness of the product.

Vacination Clinically Considered.—Dr. Frank S. Fielder then read a paper on this subject. (See p. 490.)

Remarks on the Preparation of Vaccine.—Dr. John H. Huddleston read this paper. (See p. 503.)

Vaccine Organisms.—Dr. Anna Wessels Williams said that 130 papers have been written during the last fifteen years describing supposedly specific organisms that occur in vaccinia. Fifteen of the investigators were sure that they had succeeded in isolating the specific microbic cause of the disease. These specific micro-organisms were of all kinds, forms, and types. There were bacteria, ferments and protozoa. All these supposed discoveries with one exception have been rejected by critical bacteriologists. Some of the reported results that are constantly cropping up in the medical journals are amusing for their utter ignorance of the results obtained by others. Only last May an investigator seriously claimed to have discovered the bacillus of vaccinia. Any bacteriologist at all familiar with the subject recognized at once that the organism to which this writer referred was an ordinary saprophyte that is practically always found in vaccine material.

The Question of Protozoa.—The claims of only one micro-organism have not been disproved. This is seen in certain appearances which are found in epithelial cells in the neighborhood affected by vaccinia. When vaccine material, containing these appearances within the cells, is inoculated into the cornea of rabbits corresponding changes occur in the corneal cells. It is as yet an unsolved problem as to whether these appearances are due to micro-organisms or are merely degenerative tissue changes. Pfeiffer claims that these appearances are due to a protozoon, the presence of which is to be detected in the lesions of vaccinia, variola and varioloid. He

thinks he has detected a certain motility in the micro-organisms and is sure that they grow in size and number with the age of the lesions. Other observers claim that the appearances noted are due to degenerative intracellular changes which cause certain parts of the protoplasm of the cell to take the stain in a different way to the rest of the cell.

Personal Experience.—Dr. Williams has found the appearances that are said to be those of the microbe in question in corneal cells thirty-four hours after the injection of material from vaccinal lesions, which also contained these appearances. The characteristic intracellular bodies were noted especially before the leucocytes had gathered in any numbers. Leucocytes apparently prevented the further growth of the micro-organism. Usually one of these supposedly protozoic bodies was found near the nucleus of the cell. At times two were to be seen and there were signs of recent division having taken place. In vaccinal lesions these bodies are found everywhere excepting in the stratum corneum of the skin. They occur especially in the hair-follicles and in the sebaceous glands, the epithelial cells of which seem to furnish a proper habitat for the protozoon. At times the protozoic body is as large as the nucleus of the cell and it may cap it or shove it aside. These bodies disappear in five days from the calf's and in eight days from the rabbit's cornea. A series of experiments and observations undertaken in conjunction with the New York Board of Health shows that whenever these bodies occur in vaccine material the virus is active and is capable of producing vaccinal immunity. Where these bodies do not occur the vaccine matter fails to take satisfactorily.

Revaccination.—In discussing the papers on vaccination, Dr. W. A. Dunckel said that the question of revaccination is the most important one for the medical world now. It has been demonstrated that the protection afforded by vaccinia may run out even in five years. The effect of vaccination on other skin eruptions is exaggerated. Dr. Dunckel saw recently a tuberculous, pustular eruption widely distributed develop just ten days after vaccination. Besides this tinea occurred on the face and head. The case was a puzzling one, and the history seemed to point to the existence of syphilis. Investigation proved that this was the cause and the therapeutic test confirmed this diagnosis.

Vaccination Shields.—Dr. Dunckel expressed himself as thoroughly opposed to the use of shields. The protection afforded is very slight while the chances of infection are added to. Almost any form of shield leads to some constriction of blood vessels and causes the vaccinal ulcer to run a slower course and to cause deeper destruction of tissue than would otherwise occur.

Dr. Dunckel has seen a recrudescence, after a second inoculation had been made, of a vaccine inoculation which apparently was not going to take. This recrudescence took place when the original inoculation was nine days old. Both inoculations took at about the same time and ran their course together. Such delay is unusual, but must be remembered. In about fifty per cent. of the cases of children whose mothers were vaccinated after the seventh month of intra-uterine life was passed, vaccination immediately after birth did not take. Barlow has shown that vaccination on a supernumerary finger, the finger being removed on the third day after inoculation practically never failed to take.

Dr. Bartlett said that sixty to seventy per cent. of children vaccinated in infancy may be revaccinated successfully between the ages of eight and thirteen years. In recent years we have learned that the glycerinated vaccine virus is much more effective than the fresh untreated virus. Certain cases of vaccination produce a keloid excrescence in the skin. The protective power of this is almost nil. These unusual forms of vaccination scar have become much less frequent of late years. Failures to take are also much more rare. Last year in a large number of vaccinations from January to June, Dr. Bartlett had not a single failure. During the month of June there were eight failures. It is evident that the warm weather modified the virus sufficiently to prevent its being as effective as usual. The Board of Health vaccine virus has been most efficient. For a while when it was difficult to procure Board of Health virus because of the demand, some virus from a private source was employed. This did not prove so satisfactory. The number of marks made at the original vaccination seems to make very little difference. One successful inoculation seems as effective as three.

Defense of Shields.—Dr. Bovaird said that he has had excellent results from the use of shields. They practically do away with all the discomfort of vaccination and so tempt parents to have their children vaccinated more readily than would otherwise be the case. He uses a stout wire shield 2½ inches in diameter, which is applied by means of rubber adhesive plaster, or still better by means of zinc oxide plaster. When firmly put on in this way it remains for three or four weeks and proves a thorough protection for the vaccine ulcer all during its course. If necessary it may be renewed and it should, of course, occasionally be seen by the doctor. The best proof of its usefulness is the testimony of patients as to the comfort experienced in revaccination. People have noticed so much difference between the discomfort felt at the previous vaccination and at this one protected by a shield that they have considered the latter method a great improvement.

Against Shields.—Dr. Kerley said that he is opposed to the use of shields. During the present winter he has done about 700 vaccinations in private practice. Only in cases in which sheilds were used were there any sore arms. Shields were used by certain patients contrary to his advice. In nearly every one of these cases the vaccination ran a longer, severer course than in those in which the inoculated spot was left unprotected. The manner of putting on shields produces too much tension, disturbs the circulation in the neighborhood, makes the tissues more liable to break down, prolongs the course of healing, and leaves a deep scar.

Number of Inoculations.—In closing the discussion Dr. Fielder said that we do not know whether inoculation at several points produces better protection than inoculation at a single point. As much vaccinal material can be put into one well bared spot as into three very small ones. Immunity and susceptibility seem to be absolutely indifferent to the number of scars that exist provided one good scar surely is present. It is probable that there is some slight protection afforded by the raspberry excrescence, but this is only temporary. Such patients sometimes fail to take on immediate revaccination, but after a month or six weeks, revaccination is usually successful.

Aseptic Skin.—It is practically impossible to produce absolutely aseptic skin for the place of inoculation. Antiseptics may be used freely, however, in washing the skin and they will not interefere with the action of the virus if it is good. Washing with 1-1000 bichloride has been employed without interfering in the slightest with the success of the vaccination. As a rule it seems sufficient to clean the arm thoroughly with alcohol. Any one who has done many vaccinations, however, will remember cases in which the vaccination on dirty arms ran an absolutely uncomplicated course, while after the most thorough cleansing, infection is sometimes noted almost before the vaccination itself begins to take. Beneath shields it is not unusual to have macerations of the skin occur and then maceration of the underlying tissues is a result of the failure of ventilation. These conditions may even lead to the development of a running sore that takes a long time to heal.

Undoubtedly vaccination during pregnancy has some influence on the child then being carried. Twelve out of fifty infants vaccinated under these conditions prove refractory to vaccination. In no individual case, however, can this be depended on for protection and children must always be vaccinated as more than three-fourths of them are susceptible. A German observer has noted that forty-four out of fifty children born under this condition had some slight immunity, but this does not suffice as a safeguard.

Shields Harmful.—Dr. John H. Huddleston said that as the result of his experience he is utterly opposed to the use of shields. The only bad arms he has seen were in cases where shields had been employed. As a matter of fact the physician should watch at intervals of several days the course of the vaccine ulcer. Most mothers hesitate to dress an ulcer or have anything to do with the care of it, but put it under a physician's care. Somehow, however, the vaccine ulcer is supposed to be an exception. It is cared for at home, or no attention at all is given to it, until serious complications set in.

The individual reaction to vaccination is very different. In two cases where the vaccination takes promptly and effectively one will have scarcely any sore, the other considerable loss of tissue. The use of disinfectants before inoculation with vaccine material seems to have very little effect in protecting an individual from secondary infection. Infection when it takes place occurs after the vaccine ulcer has been established. The size of the area scarified for vaccination is important. Where the area is large more necrosis takes place and more opportunity for infection is afforded.

Vaccine Organism.—The question of the microbe of vaccinia is of course extremely interesting. The bodies described by Dr. Williams that occur in certain cells during the course of the vaccination represent very probably the best claimant as the microbic cause of the disease. In this matter some very interesting experiments have been done on the horse. The horse is refractory to vaccination and one is not sure of always obtaining a successful result. It is only when the bodies described by Dr. Williams occur in the equine tissue that there is any assurance that the vaccine matter furnished by the horse will surely communicate vaccinia. Where these bodies do not occur no true vaccine material is manufactured.

MEDICAL SOCIETY OF RUSH COLLEGE.

Stated Meeting, Held February 4, 1901.

Anatomy of Pregnancy.—Dr. J. Clarence Webster demonstrated specimens illustrating the anatomy of pregnancy as studied by frozen sections; also a specimen of ruptured uterus removed from a woman in whom there had been a neglected impacted face presentation.

Acute Intussusception.—Dr. Philip Schuyler Doane reported a case of acute intussusception in an infant with operation and recovery. Relapse in three and a half months with second operation and recovery. A healthy, female child, three months old, screamed out suddenly with severe pain,

turned pale, was somewhat cyanotic, began to vomit. Three hours later there was a passage of blood and mucus *per rectum*. The pulse was rapid and weak; temperature, sub-normal. A mass was detected in the ileocecal region. There was no reduction of the tumor after a high rectal enema. Seven hours after the first symptom an operation was done by Dr. F. Henrotin, in whose practice the case occurred, and a single intussusception was found, about fifteen centimeters of the small intestine with a portion of the cecum being invaginated into the large intestine. This was easily reduced and the child made an uneventful recovery. Three and a half months later there was a recurrence of the intussusception, the symptoms being so like the first that the mother made the diagnosis and hurriedly summoned a physician. An operation was done ten hours after the first appearance of pronounced symptoms, the child being in a serious condition. No reduction of the intussusception which was found after the abdominal incision was possible by injection of air into the intestine. After considerable difficulty, the invagination was reduced. The partially gangrenous appendix was removed and three stitches of fine catgut were then placed in the walls of the ileum and cecum, near their junction in such a way as to make almost an acute angle. The child made a good recovery. She was seen by Dr. Doane seven months after the operation and was apparently in perfect health. The importance of very early diagnosis and immediate operation was dwelt upon.

Pseudo-Phosphaturia with an Unusual Complication.— Dr. Alfred Schalek said that true phosphaturia is a pathological condition in which an excessive amount of phosphates is excreted. It is due to some disturbance of the general metabolism. Systemic symptoms are usually present, such as general or local neuroses, disturbances of the gastro-intestinal organs, general fatigue and loss of flesh. If free urination is prevented in some way, calculi may form in the kidneys or the bladder. Other local complications are rarely mentioned in the literature. A case is cited here, in which phosphatic deposits, consisting of large masses of amorphous phosphates of lime, were persistently present in the urine, the time extending over three years. The white sediment formed in the bladder and amounted, by sight, to about one-quarter of the volume of passed urine. The urine was alkaline from fixed alkali. The patient was decidedly neurasthenic, and lost twenty-five pounds in weight after the phosphaturia began. During all this time he suffered from a purulent urethral discharge, which may have been originally of gonorrheic origin, but which while under observation on repeated examinations never revealed any gonococci. This, and the fact that no lesions were found in any part of the genito-urinary tract, with the coincident presence of the phosphates in the urine, led to the conclusion that the latter were the cause of the irritation of the urethral mucous membrane. Various attempts were then made to correct this anomalous feature. Urotropin finally accomplished this, though only during the time of its administration. The urine cleared up and shortly afterward the urethral discharge disappeared. Several times the urotropin was discontinued, with the consequence that the whole cycle of symptoms reappeared. This proved the relation between the phosphaturia and the urethritis. The rationale of the action of the urotropin upon the excretion of phosphates is obscure. It is too weak a base to influence the reaction of the urine; neither can its antiseptic properties be taken into account in the absence of any pathological conditions of the genito-urinary passages. The quantitative analysis gave the rather surprising result that the amount of phosphates was normal, in spite of their persistent deposition in the urine and their obvious effect upon the general system.

BOOK REVIEWS.

A Clinical Treatise on Fractures. By William Barton Hopkins, M.D., Surgeon to the Pennsylvania Hospital, and to the Orthopedic Hospital and Infirmary for Nervous Diseases. J. B. Lippincott Company, Philadelphia.

In this volume the author has given his views and ideas on the treatment of fractures in all parts of the body. He also discusses the etiology of the different kinds of fractures, and the deformities as he has observed them, as well as the points of diagnosis. The treatment is given very clearly and concisely, and forms the greater part of the book. The volume is profusely illustrated by photographs and skiagraphs. The book, however, is printed upon such thick calendered paper that it is unpleasant to handle.

Encyclopedia Medica. Edited by Chalmers Watson, M.B., M.R.C.P.E. Vol. V.: Herpes to Jaws; Vol. VI., Joints to Liver. Longmans, Green & Co., London, New York and Bombay.

The scope of this Encyclopedia has been sufficiently indicated in our reviews of the previous four volumes. Among the more notable articles in Vol. V. may be mentioned those on Hysteria, Hip-Joint Disease, a most excellent discussion, Hypnotism and Diseases of the Intestines. The subject of Immunity is very thoroughly treated, as is also that of Hypnotism and Invalid Feeding. This last topic is most carefully and elaborately gone into. The illustrative features of this volume are not worth mentioning.

In Volume VI. the subjects of Diseases of Joints, Kidney Affections, the Larynx and Its Diseases, Labor and Leprosy, practically take up the entire space. The discussion of Labor is

lengthy and excellent, but miserably illustrated. The practical features of the work are still in evidence. There is much to be desired in the more strictly technical and scientific features of the work. Here the work often lags behind our standard text-books. We note the continued absence of any mention of any drugs or anything bearing on pharmacotherapy.

The Practice of Medicine. A Text-Book for Practitioners and Students, with special Reference to Diagnosis and Treatment. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania. Second Edition. P. Blakiston's Son & Co., Philadelphia.

There is little to be said in further comment on this, the second, edition of Tyson's Practice than was said in our review of the first edition. It is a work creditable to both writer and publisher alike. The changes which have been made in this new edition have been mainly in the chapters on the infectious diseases and the nervous system. The necessary changes incident to the rapid increase in knowledge concerning bacteria have been made and the section on the infectious diseases, from a descriptive standpoint, at least, compares very favorably with anything we have in the English language.

The section on diseases of the nervous system has been entirely recast. It is a thoroughly trustworthy guide to the student and is particularly commendable in that so much information has been compressed into comparatively few pages. The discussion on cerebral hemorrhage is above the general average text-book presentation of this subject.

Therapeutics: Its Principles and Practice. By Horatio C. Wood, M.D., LL.D. Eleventh Edition. Remodeled and Rewritten by Horatio C. Wood and Horatio C. Wood, Jr., M.D. J. B. Lippincott Company, Philadelphia and London.

It is a tax on the reviewer's ingenuity to be able to say anything new when an eleventh edition is under consideration and for the most part it is unnecessary when such a veteran as this is to be discussed. There are, however, some radical departures from the older editions in this new one. With such as are concerned with a change in form, the reader is little interested, although the cumbersome style, which was the inevitable result of the interpolations due to successive revisions, was a distinct drawback to earlier texts. The entire rewriting of the text, therefore, in this edition has given it a continuity which before it greatly lacked. The peculiar choppy sentences of the older editions, cut up as they were with references to all the old monographs, have disappeared and there is presented a continuous account of the subject which is much more easy to read.

Another feature, which will undoubtedly prove of service to the busy man, is the short summary, printed in heavy type, which accompanies each drug. This adds a pedagogic value to the work which has always been lacking. It makes it a work for students as well as for specialists.

In this new recasting the work regains its old time position, as perhaps our best exponent of the practice of rational therapeutics.

Text-Book of Physiology. Edited by Dr. E. A. Schafer; Professor of Physiology, University of Edinburgh. Volume II. The Macmillan Company, New York.

At the outset it may be said that we consider this the best text-book presentation of the subject-matter of physiology extant, recent Continental text-books notwithstanding.

One of the reasons for this statement is the wide cosmopolitanism shown in the individual chapters. The separate sections are treated by men of acknowledged reputation and in their mode of handling the subjects, they have left little of value unstated and have reduced many physiological monographs to their essentials.

Comparisons are out of place in a discussion of the merits of the different sections, but special praise is due to the editor for his able handling of the intricate subject of the nerve-cell and to Drs. Langley and Sherrington for the chapters on the sympathetic nervous system, the spinal cord and lower cerebral centers. Dr. Langley's chapter on the sympathetic and its relations is particularly valuable at this time when epoch-making researches in this field of physiology are imminent. An interesting and instructive chapter on the physiology of electrical organs is contributed by Dr. Francis Gotch and the discussion of the nature of the electrical reactions to nervous stimuli is suggestive and timely. Hill's study of the mechanism of the circulation of the blood is a most valuable chapter, based largely on Tigerstedt's masterly monograph.

The publishers' part has been most admirably carried out. These volumes are indispensable to the physiologist, necessary for the student and of supreme value to the practitioner.

Appendicitis and its Surgical Treatment, with a Report of One Hundred and Eighty-Five Operated Cases. By Herman Mynter, M.D. J. B. Lippincott Co., Philadelphia.

This is the third edition the author has brought out and it has been thoroughly revised and brought up to date. The histories of the cases have been omitted in this edition and in their place a classification according to their different forms has been substituted. The volume opens with a historical introduction, and the anatomy and histology of the appendix are minutely described. Under etiology, some of the predisposing causes mentioned are indigestion, constipation, previous attacks,

movable kidney, and constitutional disturbances, *e.g.*, tuberculosis, rheumatism, typhoid, dysentery, etc. Exciting causes are coproliths, foreign bodies, microbes, strictures, kinks and mechanical obstructions. Under pathology he makes use for descriptive purposes of three forms, simple catarrhal, ulcerated, and infectious appendicitis.

Clinically he distinguishes simple appendicitis, appendicitis with perforation and local circumscribed abscess, appendicitis with gangrene without perforation, appendicitis with gangrene, perforation and diffuse peritonitis, and chronic recurring appendicitis. The symptoms most frequently present are pain, tenderness to pressure, vomiting, constipation, rigidity of the abdominal muscles, tumor, chill, fever, costal respiration and leucocytosis. The treatment advised is surgical. The sooner these cases are operated on, the better, especially those beginning with acute pain, vomiting, rigidity, and fever which does not recede inside of twenty-four hours.

In this work the author has given us the conclusions arrived at by many of the surgeons, not only at home but abroad, and credits the Americans with first recognizing the fact that the disease is one for the surgeon to deal with exclusively. Its pages can be read with profit by both the surgeon and the general practitioner.

A Manual of Medicine. Edited by W. H. Allchin, M.D., F.R.C.P., London. The Macmillan Company, New York.

This is the second volume of Professor Allchin's Manual and contains a continuation of the subject of general diseases. The principal contents are diseases caused by parasites, diseases determined by poisons introduced into the body, primary perversions of general nutrition and diseases of the blood.

The chapters on obesity, on diabetes mellitus, on gout, on rheumatoid arthritis and on myalgia are very interesting, practical résumés of the present state of our knowledge with regard to these important but obscure conditions.

In the discussion of chronic rheumatism it seems too bad that more weight was not laid on the fact that careful differentiation will exclude, most of the symptoms ordinarily called rheumatic from any connection with chronic rheumatism. Most of the recurrent pains of patients beyond middle life are not rheumatic in origin, but are due partly to occupation neuroses, partly to injuries in early life and consequent interference with peripheral nerve nutrition and partially to vasomotor disturbances with a neurotic basis.

On the whole, this second volume maintains very well the thoroughly practical character of the first volume and gives promise that this set of handy medical manuals will be of distinct service to the practitioner

Ophthalmic Lenses, Dioptric Formulæ for Combined Cylindrical Lenses. The Prism-Dioptry and Other Optical Papers, with 110 Original Diagrams. By Chas. F. Prentice, M.E. "Opticist." Published by the Keystone, Philadelphia.

Without question figures, like those so generously employed by the author in the text of his papers, help the understanding. There is also undoubtedly a fair number of readers who wish for just this help in the optics of refraction, all the more because the ground covered is the least familiar to the average oculist. Therefore, we think many oculists will desire to possess and study this book. Yet, we must confess to a belief that not many of them will relish the complicated trigonometrical formulæ employed in Section II. to show the behavior of combined cylindrical lenses. Section III. has forces of a more practical character in its treatment of prism-dioptry, measurement of prisms, prescription of prisms, sphero-toxic lenses and refraction in presbyopia. The author deserves a fair meed of praise for these papers put together in such excellent form.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Diseases of the Anus and Rectum. By Drs. D. H. Goodsall and W. E. Miles. Part I. 8vo, 310 pages. Illustrated. Longmans, Green & Co., London, New York and Bombay.

The Nursing Profession. How and Where to Train. Edited by Sir Henry Burdett. Demi 8vo, 370 pages. The Scientific Press, London.

A Medico-Legal Manual. By William M. Keysor. 8vo, 317 pages. Burkley Printing Company, Omaha.

The Essentials of Practical Bacteriology. By Dr. H. J. Curtis. 8vo, 289 pages. Longmans, Green & Co., New York, London and Bombay.

An Introduction to Physiology. By Dr. W. T. Porter. 12mo, 314 pages. Illustrated. The University Press, Cambridge, Mass.

International Clinics. Edited by Dr. Henry W. Cattell. Vol. IV., 1901. 8vo, 312 pages. Illustrated. J. B. Lippincott, Philadelphia.

Transactions of the Mississippi Valley Medical Association. Twenty-sixth Annual Session. Vol. II., 1900.

Thirtieth Annual Report of Board of Commissioners of Public Charities of the Commonwealth of Pennsylvania for 1899.

The Year-Book of the Nose, Throat and Ear. Edited by Drs. G. P. Head and A. H. Andrews. The Year-Book Publishers, Chicago.

The American Year-Book of Medicine and Surgery for 1901. In Two Volumes. Edited by George M. Gould. W. B. Saunders & Company, Philadelphia and London.

Obstetric and Gynecologic Nursing. By Dr. E. P. Davis. 8vo, 402 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

ADVERTISING IN THE PROFESSION.[1]

BY G. FRANK LYDSTON, M.D.,
OF CHICAGO;
PROFESSOR OF THE SURGERY OF THE GENITO-URINARY ORGANS, MEDICAL DEPARTMENT, ILLINOIS STATE UNIVERSITY; PROFESSOR OF SURGERY, CHICAGO CLINICAL SCHOOL.

THE subject of advertising in the profession is entirely too broad for consideration in a single paper. It is one of the most vital questions pertaining to latter-day medical practice. We may enact the rôle of the ostrich with his head in the sand as much as we please, but the advertising problem is one from which we cannot escape. Perhaps if we follow the example of the ostrich, the problem might not stare us in the face, but, to use an Irish bull, it would still confront us. Time was when the question of professional advertising was simplicity itself. Those of us who graduated twenty or more years ago will recall that the commandment, "Thou shalt not advertise," covered the ground without any apparent necessity of hair-splitting niceties of distinction. On entering practice, however, we found things differing from our ideal. We found that that ideal was more often honored in the breach than in the observance. We found that we had taken the medical eleventh commandment too literally. Its correct interpretation should have been, "Thou shalt not be caught advertising, nor shalt thou pay for it openly." We very quickly discovered that living without advertisement in the practice of medicine was all moonshine, that we were compelled to advertise in one way or another or starve. The exigencies of the situation have from year to year increased the necessity of advertisement, have lessened opportunities for surreptitious advertisement, and compelled the adoption of methods on the part of some of our brethren whose motto, "Get there, Eli," would cause a Chatham Street Jew to blush.

Our medical forefathers gazed complacently upon the code of ethics as containing all that was good and pure and holy in the medical faith.

All the evidence goes to show that times have vastly changed since the code was written, and that the profession is surreptitiously trying to adapt itself to that change. In this endeavor it is perhaps by no means surprising that certain members of the profession have gone to the last extreme and adopted methods which put out-and-out advertising to the blush. The struggle for readjustment of our ethical notions will continue until out of the chaos of dishonest commercialism and shady methods comes a practical system of medical ethics that shall contain fewer inconsistencies and fewer absurdities than the code by which we have professed to be regulated for many years. It is a singular fact that the latter-day physician and surgeon has shown a tendency to adopt lines of conduct removed to the farthest extreme from the code. When backsliding began it seems to have progressed with a vengeance. Pecksniffs a plenty there may have been among past supporters of the ethical interpretation of the code, but nowadays the Machiavellis outnumber the Pecksniffs.

It is my belief that "Thou shalt not advertise," was of necessity written in a Pharisaical spirit, and that it has been the cloak of more inconsistency and hypocrisy than anything ever written for the guidance of medical men. Whatever the conditions may have been at the time the code was written—and I do not believe they differed in kind from those prevailing at the present day—conditions nowadays absolutely demand advertising of one kind or another on the part of medical men. The physician may gloss this necessity over, and he may deceive himself into the belief that he is not given to advertising, but the fact still remains that he must advertise or starve. All roads lead to Rome, and it is by no means necessary that the physician should advertise in the newspapers or by handbills, in order to accomplish his ends; nor does it follow that he is unjustified or unworthy of respect because under the stress of his environment he advertises in one way or another. If the opinions of those who champion the cause of the commission-giving and commission-taking doctor should be accepted by the profession, it would no longer be possible to classify advertising on the part of physicians. There is nothing lower in the scale in advertising than the commission business. Give the medical man the privilege of sending out paid agents, or employing professional drummers on commission, and he will have nothing more to conquer in the world of advertising. Commission practice, in point of effectiveness, bears the same relation to ordinary advertising that accurate rifle-shooting does to inexpert shotgun practice. With the professional drumming sleuth on the trail of an operation case, it is hardly possible that it could escape. I believe, however, that the reputable members of the profession discountenance such methods as those involved in commission-paying, commission-receiving, and medical and surgical drumming.

The most important forms of professional advertising are college advertising, medical writing, social advertising, church advertising, secret society advertising, and that indefinable something

[1] Read before the Physicians' Club of Chicago, January 28, 1901.

known as newspaper prominence, which is called advertising by the fellow who can't get it, and is considered a laudable enterprise by the fellow who does—the old story of the pigs in the clover patch. As is true of all other affairs in human life, it is a noteworthy fact that it is the pigs outside the fence that do most of the squealing.

It would require a book to do justice to the various phases of advertising; besides, we are all treading on thin ice, and if the subject were threshed out too thoroughly some of us might slump through.

College and hospital advertising affect us most. The necessity of obeying the spirit while violating the letter of the code upon advertising, has been the chief factor in the multiplication of medical colleges. I am well aware that most teachers pose as philanthropists. They would not advertise for the world—that is, unless they thought they could get the world. But I have no hesitancy in saying that self-advertisement is the foundation stone upon which the average college teacher builds his hopes. I do not say that this is true of all—for some are salaried—but I have mighty little respect for the fellow who claims that he is teaching for the love of humanity, believing as I do that Charles Lamb, or whoever it may have been, was correct when he said, "Humanity is I, writ large." Colleges have multiplied to such an extent that one of the best advertisements a man can have in the profession nowadays is that he is not a professor. If colleges keep on multiplying, as they have during the last few years, our medical teachers will be "professors" indeed. There will not be enough students to go round, and our teachers will have nothing to do but—"profess."

I have no doubt that in former days the advertisement incidental to college teaching was more or less profitable to the incumbent of a Chair, and I suppose every man, who has been teaching for a number of years, thinks that it is still profitable. It is not really profitable, however, because very few men who occupy college positions are gleaning greater financial rewards from their practice than they would now be doing had they never connected themselves with a medical school.

The time is approaching when the medical profession will be compelled by its own necessities to limit the number of medical colleges and the number of medical students. The medical teacher is engaged in two evils: (1) Educating competition to himself and others. (2) Inducing young men to enter an already overcrowded profession. Ere long the medical man will become inspired by a spirit of professional altruism and will do his utmost to prevent young men entering the profession of medicine. The output of medical graduates must be checked, else the profession will be reduced to the same pitiful plane that it occupies in certain European countries. So keen has competition become that teachers in certain colleges are now cutting each other's throats, so to speak, in order to obtain, shall I say practice, or business? I will illustrate by citing a hypothetic case.

A hypothetic medical school in a presumptive great metropolis has in its faculty, we will say, a round half-dozen (mind you, I do not say a square half-dozen) surgical teachers. Some of these teachers are content to let their work speak for itself, and to appeal to the Alumni of the institution only through their ability as teachers and operators. A certain proportion, however, of the aforesaid coterie of surgical teachers bids for the patronage of the Alumni of the institution by offering a commission of fifty per cent. on all surgical cases referred to them.

It would be interesting to know in what way the work of a surgical teacher who does not prostitute his position can become profitable to him with such degrading competition so near him. It would also be interesting to know of what value surgical instruction is to the graduates of such a school after they have learned from some of their eminent teachers that it is more profitable to send cases to the latter at fifty per cent. commission than it is to operate themselves. I submit this illustration to the thoughtful consideration of the profession.

The young man who starts out in practice with the intention of doing surgery commands at first relatively small fees. He may be perfectly willing to give a percentage of his fees for such operations as are brought to him; but the practitioner who has a case to "steer" says to himself: "If I take this case to young Dr. A., he probably will not be able to get more than $200.00 out of it, which will leave only $100.00 for me. If I take it to Professor B., he can get $1,000.00 out of it, which will give me $500.00." Under such circumstances, it is hardly to be supposed that the general practitioner would be like the far-famed jackass between the two bundles of hay. Can it be possible that our young medical men cannot see that such methods will eventually absolutely demoralize the profession, to say nothing of the dishonesty and degradation of such practices and the creation of a surgical trust? Many pages might be written on the subject of college advertising, but it would be difficult for me to present in a more striking manner the trend of medical college advertising at the present day.

There is, however, one point in connection with medical college positions that I wish to touch upon. It is a noteworthy fact that among European teachers it is customary to print college titles upon their professional cards and stationery. I do not suppose that they are any less ethical than we, but I submit the proposition that this method of advertising is not one whit worse than the appearance of the titles of teachers in college announcements. I believe the time has passed when it is reprehensible for the physician in

general, and the teacher in particular, to lay his wares before the possible consumer. There has been too much hiding of the professional light under the bushel of hypocrisy and surreptitious methods of advertising.

In this connection the dispensary and free clinic route to fame deserves consideration. The profession has long been suffering from moral strabismus, superinduced by gazing too fondly at the large round American dollar, which looks so near, yet is so far away. A number of men may incorporate a hospital or dispensary clinic and all is ethically well. One man, or even several men, may not organize a private concern of the same kind for advertising purposes without losing caste. It would be well for the profession at large to conduct its own free clinics. Let every man who so desires designate hours for the poor on his cards. This will do much toward killing deadbeatism, and regulating hospital and dispensary evils. Let there be one law for all!

Apropos of college and hospital positions and professional cards, I remember with some amusement an early experience of my own. I managed to muster sufficient courage to have printed upon my first professional card many years ago, "Late Resident Surgeon New York Charity Hospital." A distinguished medical gentleman in this city, after conference with an equally distinguished confrère, visited me and assured me that I was a nice young man gone wrong. I promised not to do it any more, and I fully intended to keep that promise, but a day or two thereafter I saw an item in a newspaper to the effect that my two distinguished friends had just performed "a formidable and successful operation for the removal of a sebaceous cyst, fully as large as a hen's egg," from the cranium of one of our prominent West Side citizens. I then made up my mind that the wen was mightier than the card. I did not destroy my cards.

Hospital advertising might be termed a subdivision of college advertising. What I have already said regarding the payment of commissions to college men applies equally well to hospital men, and perhaps with greater force, especially my remarks on the surgical trust.

The extreme to which college advertising, or rather, in this instance, conjoined college and hospital advertising, has been carried in certain quarters is very suggestive. It has been rather edifying to read in one of our prominent evening papers the advertisement of a certain post-graduate school in Chicago. This post-graduate school announces to all and sundry that it is prepared, not alone to teach medicine, but to teach practitioners of medicine. The names of five of the faculty are affixed thereunto. No newspaper advertiser could ask for a better thing than this. It would be interesting to know what proportion of the professional clientèle of this post-graduate school is accessible viâ the daily press. Can it be possible that the school caters only to the patronage of physicians who read no medical literature, but rely exclusively upon the advertising columns of the daily press for their intellectual pabulum? It would also be interesting to know whether the other members of the faculty were mulcted for the aforesaid advertisement. If they were, they would be justified in open rebellion.

Speaking of the value of college positions as a means of advertisement, a somewhat recent experience of my own shows that they are used by different men with varying degrees of effectiveness. It is not even necessary to have a position of one's own in order to use the college as a means of advertisement. I relate the following incident because it is really funny.

It so happened that some months since, by reason of multifarious complaints, real and imaginary, I was unable to fulfil my college duties. Without any inquiry being made as to whether the party selected would be acceptable to me, a certain individual was appointed my substitute. He immediately proceeded to prepare a course of lectures in accordance with his own notions, and without deigning to consult me as to what portion of the course remained to be covered or other little details that a man of average intelligence should have known were necessary in the premises. I meanwhile requested another gentleman to fill my hours for the remainder of the term. Substitute No. 1, upon the assurance of somebody or other that I had both feet in the grave, published his picture and life history in all the newspapers in Chicago, along with the wonderful surgical inventions with which he had blessed a benighted surgical profession and the announcement of his appointment to my Chair. He submitted a paper to the Editor of the *Journal of the American Medical Association* for publication, to which he appended the titles pertaining to my Chair. Fortunately, the paper was returned as ineligible. The medical journals, quoting from the Chicago daily papers, announced the change of professors in the college, and as I was never known to resign anything, my professional friends throughout the country labored for some time under the delusion that I was dead. Which reminds me of a rumor which once spread abroad to the effect that Mark Twain was dead in London. On hearing of it, Mark promptly sent a cablegram to this country, reading: "The rumors regarding the state of my health have been greatly exaggerated."

The extent to which the specialist may advertise his specialty has long disturbed the already over-burdened conscience of the profession.

It will be remembered that, once upon a time, when the Fool-Killer was away on a vacation, the members of a learned National

Society wrestled long with the question of Ophthalmologist and Otologist vs. Oculist and Aurist. It was finally decided that a man who printed on his cards, "Oculist and Aurist," was a goat and the sheep would have none of him. If he expressed it, "Practice Limited to Diseases of the Eye and Ear," he was a milk-white lamb with wool a yard long. I wonder how many of those latter-day saints are drumming for "business!" The profession has kept on swallowing its cud, until now one may put on his professional cards, "Diseases of Women Only." But if he print, "Diseases of Men Only," he will be brought to book for his ignorance of the comparative esthetics of leucorrhea and suppressio mensium, and spermatorrhea and varicocele.

I presume that the term social advertising is somewhat offensive to members of the profession who believe that their success in life depends upon their own intrinsic greatness. But if we are honest with ourselves, we must admit that this form of publicity and promotion is one of the most important factors in securing practice. Some are very much more expert in self-advancement in this direction than others. The man who has had a talkative wife for his advertising agent is perhaps the most brilliant success in this line, providing she talks only of his greatness and is impersonal in her discussion of his clientèle. When the endurance and mechanical excellence of a talking machine are combined with the qualities of a female diplomat in the doctor's wife, it is difficult to see how he could possibly make a failure in life. In these piping days of competition I would advise the young doctor who is ambitions for speedy success and popularity, first, to marry rich; second, if he cannot marry rich, to marry a female talking machine. One of these ladies with a few pink teas and yellow breakfasts can give her young doctor husband more of an impetus on the road to fame and success than many barrels of midnight oil. He who bloweth not his own horn, the same is sometimes blown by his wife.

Church advertising and secret society advertising are very much of the same kidney. There is merely a difference in politics. Of course, the church-going doctor, especially the man who belongs to several churches or rents pews therein, will repudiate the insinuation that he has an object in view, but that timeworn "gag" fools nobody, not even himself. Personally, in the days of my youth, I liked the secret society dodge better, perhaps because I was more familiar with it. But I wish to say right here and now that, unlike some of my more modest brethren, I never flattered myself with the unction that I was staying up nights for my health. I will frankly confess, that my ideas of the value of that sort of advertising were rather exaggerated because, I fancy, the competition was so keen.

Is there any tinge of selfishness in the aims of medical writers? I presume there are men in the profession who are possessed of sufficient egotism to believe that they are conferring a distinct benefit on humanity by all their scientific writings, and who, with this idea in mind, lose sight of the possible value of their literary work to themselves. I believe, however, that aside from the limited few of these ego-maniacs, the average medical writer, if you can involve him in a heart to heart talk, will confess that he has written primarily for No. 1. Most medical writers would devote their attention to something more profitable than literature if they felt that their efforts resulted only in self-improvement and good to humanity at large. The man who writes articles and publishes reprints is engaged in advertising. He is, however, advertising to his competitors, which is the longest possible road to the consumer and therefore tolerated by the profession. There are those in our profession, however, who are very impatient with the medical writer because of the implied attempt to advertise himself. This position is absurd. The value of literature to the reader is by no means determined by the object which the writer has in view. The man who writes to advertise himself is quite likely to give the reader his best effort, for in this field, as in every other, competition is keen. The man who throws a reprint into his wastebasket simply because he thinks the author is using his reprints as a means of advertisement makes himself ridiculous. The author in the field of general literature often gets his reward—why then should not the medical writer? The medical writer must needs content himself with the advertisement of his work. The "all hog" publisher will not recompense him. Just think of writing a text-book for a beggarly five per cent. royalty, or, as my publisher puts it, five per cent. royalty after the publisher has recouped himself, alterations and amendations to be charged up to the author. If some of us got as little fame out of our work as we do money out of our publishers, I fear the literary mill would not grind so assiduously.

The question of newspaper notoriety has caused more secret misgivings and bitterness of spirit in the medical profession than almost anything that could be mentioned. The young man who has not yet attained sufficient prominence to enable him to secure newspaper notoriety, and the old man who has been a professional vegetable all his life, alike bitterly resent any representation of their more fortunate professional brethren in the newspapers. In a general way, it may be said that only advertising quacks and the big men of the

profession are the ones to whom the columns of the newspapers are open.

The unwritten law of the medical profession, that its members should keep themselves in the background, has been the greatest stumbling-block to professional advancement. The medical profession to-day has no particular social, commercial, financial, or political importance. Why? Simply because of the bigotry and intolerance of the profession itself. I hold that every physician or surgeon who becomes important in the public eye, either socially, politically, or in commercial enterprises, is a powerful factor in the advancement of the best interests of the profession. The profession is poor; the profession has no particular "pull" in either commercial or political lines, and yet we wonder why it is impossible to get legislation against quackery and various form of medical faddism. As a matter of fact, the doctor, as such, is a nonentity in the community. The medical man who makes a political speech, or becomes identified with a successful commercial venture, or is spoken of frequently and in a complimentary way by the newspapers, immediately becomes a target for the abuse and invective of the profession at large. This condition of affairs must change. I hold that it is the duty of every man in the profession not only to himself, but to the profession, to bring himself before the public, as a citizen and a representative of the profession, where it can be done respectably, at every possible opportunity. The doctor should take interest in politics. He should be a man of affairs. If he accumulates wealth, the profession should not consider it a high crime and misdemeanor, but a distinct advantage to the profession at large. By proceeding along these lines the time will come when we, as a profession, can command legislation, instead of being compelled to beg it like a lot of mendicants as we are at the present time. The quack has votes; the quack has money; the quack has pull and newspaper influence, and we have nothing; not even the gratitude of the people to whose welfare we devote the best years of our lives.

In speaking in favor of newspaper representation of medical men, I do not mean that they should publish their operations or premature accounts of alleged wonderful discoveries in the papers. The example set by certain Eastern surgeons, men of the highest prominence, in inviting reporters or permitting reporters to be at their operative clinics, cannot be too strongly condemned. I believe, however, that signed articles of a quasi-scientific character by medical men, from which the public can derive intelligent information on scientific subjects—and particularly matters medical—first hand, should be considered ethical by the profession. There is only one way to down quackery, and that is by educating the people to an intelligent understanding of what we are and what we are doing. The public is bound to make comparisons, and if it has any data upon which to base such comparisons, the quack will have much less advantage in the competition than he now possesses. We expect too much of the public. We expect it to draw hard and fast lines between quackery and legitimate medicine, while the quack is stating his case and the medical man is retiring behind the bulwark of his professional ethics and dignity.

As for new discoveries, it is high time that the frantic rush into print of the original investigators, so-called, who has discovered a lot of things that "ain't so," should be stopped. A newspaper account of a wonderful discovery was recently published, which was based upon experimentation with a borrowed apparatus on a single dog, the day before.

Careful, conscientious work and good results, bringing as they do in their train the good will and approbation of the laity, constitute the best advertisement that the physican can have. We all know this, but "first catch your hare." In order to do good work, and get good results, we must have patients, and it is the attributes that the public thinks we possess rather than those which we do possess which bring us our patients. The layman comes to each of us because he thinks we are as good or better than our neighbors in the profession. Those of us who are conscientious know how often the layman deceives himself. Be that as it may, however, the profession must first catch its hare by some sort of advertising, else its prospects of a dinner will be slim indeed.

RESECTION OF THE CERVICAL SYMPATHETIC.*

BY HOWARD J. WILLIAMS, A.M., M.D.,
OF MACON, GA.;
SURGEON TO THE MACON HOSPITAL, ETC.; EX-PRESIDENT MEDICAL ASSOCIATION OF GEORGIA, ETC.

For the clinical history of the following case, the privilege of operating, and much valuable assistance during the operation, I am indebted to my friend, Dr. J. H. Shorter, Ophthalmologist to the Macon Hospital.

T. P. W., white male, aged eighteen years, received a perforating lacerated wound of the cornea and iris of the right eye in 1887. Sympathetic trouble began in the left eye in September, 1894. For this latter condition he received antiphlogistic treatment to the left eye, and enucleation of the right globe. In June 1897, vision—$^{20}/_{100}+$. One year later cataract had developed, further impairing vision, while the tension of the globe had increased to +2. Iridectomy was then performed with partial success in reducing the tension. Later tension again increased. At the time he was referred to me for operation, July 5, 1900, he was suf

* Written for the Southern Surgical and Gynecological Association, Atlanta, Ga., Nov. 13, 1900.

fering from secondary glaucoma dependent upon sympathetic iridocyclitis plastica; vision was reduced to light perception and there was continued increase of intra-ocular tension, + 2. There was circumcorneal injection and more or less pain in and around the left eye.

On July 7th he was anesthetized by Dr. Derry, and, assisted by Dr. Shorter and Dr. Carswell, I performed Jonnesco's operation, resection of the superior cervical sympathetic ganglion. An incision, about three inches long along the posterior border of the left sternocleidomastoid was made from the mastoid process to about the middle of the neck, just missing the external jugular vein. Behind the sternocleidomastoid the tissues were separated, exposing the trapezius muscle; the sheath of the carotid containing the artery, the internal jugular vein, and the pneumogastic nerve was found. Back of the latter and separated from it by the thin carotid sheath the ganglion was located lying on the major rectus-capitis muscle. So close together were the two nerves, and so nearly of the same size and appearance, that there was some hesitancy in deciding between them. By alternately pinching them and watching the effect on the rapidity of the pulse, the pneumogastic was recognized and dropped. Stripping the sympathetic ganglion and cutting away its branches, its lower end was severed from its continuation below, then with curved scissors the upper end of the ganglion was cut just as it emerges from cranium. The wound was then closed and properly dressed.

Within a few minutes the conjunctiva was greatly congested, the eyes suffused with tears, slight left lateral sweating, with redness of the side face and ear, began, and there was some flow of nasal mucus. The next day the patient had reacted well, pain in and around the eye was relieved, there was ptosis of the left eyelid, but owing to fixation of the iris to the capsule of the lens, no change of the pupil was observed. In addition to the above symptoms, there was complete anesthesia of the left ear and marked huskiness of the voice. The conjunctival injection, the lacrimation and nasal discharge gradually disappeared.

July 16th, when he was discharged from the hospital, intra-ocular tension had reduced from + 2 to normal, pain was entirely relieved and the patient claimed improvement in vision. Ptosis had slightly increased, and the globe had receded to some extent. The voice continued husky, due, it was found by the laryngoscope, to paralysis of the left vocal cord, while anesthesia of the lobe of the ear was still present.

October 26th, Dr. Shorter reports that tension remains normal and that the field of vision is widened, but that he can find no improvement in acuteness of vision. The patient, however, stoutly maintains that he does see better and is urgently awaiting a promised operation for removal of the cataract by Dr. Shorter. He has had no pain since the operation. Ptosis is still present, though improving; the anesthesia of the ear and paralysis of the vocal cord is almost entirely relieved.

It must be understood that the two last symptoms are not dependent upon the sympathectomy, but were the results of unintentional wounds of special nerves, occurring in the course of the operation, and are not necessarily present in every operation.

Before beginning the discussion of my subject, I wish to distinctly state that this operation was not undertaken with any hope of improving the sight of this patient, but it was performed solely to relieve the pain in the eye and reduce the tension of the globe, thereby saving what vision there was from the destructive effect of a gradually increasing glaucoma. If there has been any improvement, it is more than we expected, for the opacity of the lens and its capsule is the main barrier to vision in this patient.

Division of the sympathetic nerve in the neck is an old experimental operation employed by physiologists to demonstrate the action of the sympathetic nervous system on the vegetative life of animals, its control over the vaso-constrictors in organs and tissues and its influence on the involuntary muscular system. Claude Bernard in 1851 first demonstrated that vascular congestion and increased secretion followed section of the sympathetic nerve. Jonathan Hutchinson, in 1866, recognized the ocular symptoms attendant upon paralysis of the superior sympathetic ganglion. Jonnesco and Floresco,[1] applying the technic of experimental research to patients about to have resection of the cervical sympathetic performed, have demonstrated the identity of the functions of this nerve in man and animals.

Irritation or stimulation of the superior cervical ganglion causes pallor of the head, dilation of the pupils, and prominence of the eyeballs; irritation of the inferior ganglion accelerates cardiac action; while stimulation of the middle is supposed to hasten the thyroid circulation; less is, however, known of the thyroid sympathetic control. Section of the superior nerve causes congestion of the head, lowered tension in the eye, paralysis of the dilators of the pupils and of the smooth fibers of the upper eyelid; retarded pulse follows section of the lower ganglia. Unilateral warmth, flushing, sweating, lacrimation, increased nasal secretion and saliva are the transitory symptoms of unilateral section of the first ganglion; the permanent symptoms, regardless of disease, are narrowing of the pupil, ptosis and retraction of the bulb.[2]

Reasoning from its physiological effects for its therapeutic results, sympathectomy has been undertaken for the relief of glaucoma, exophthalmic goiter and epilepsy. Recently it has been performed in vertigo of cerebral

anemia (once), and essential migraine (once) by Jonnesco, in facial neuralgia (three times) and spasmodic torticollis (twice), once by Chipault[3] and once by Kalmus[4] all reporting successful results. As a surgical procedure, it dates its birth practically from 1895, and its value is still in doubt, awaiting for its answer the test of time.

Abadie, basing his deductions on the theory that glaucoma is dependent on vaso-constriction, was the first to advise resection of the supreme ganglion in order to overcome the tension of the circulation in the eye in this disease. Dilatation of the arteries resulting from the operation, the blood-pressure is thereby lowered and extravasation is diminished; the pupil becoming contracted, the iris angle and the secretory canals are relieved of pressure, giving the aqueous humor a ready means of escape; and, further, the peribulbar muscles are relaxed, thus relieving the venous circulation. More blood circulates through the eye and the orbital region, nutrition is improved, and waste products are more readily removed.[5]

In addition to the symptoms always present on section of the sympathetic, there is in glaucoma immediate relief of pain; intraocular tension falls in a few days to normal or below, and improvement of vision begins. In some cases tension is relieved at once. Zimmerman noted in one case a fall from 2½ to much below the normal just after the operation; Dr. J. M. Ball of St. Louis[6] in one case saw it fall from + 2 to + 1 in twenty-four hours, and in a second case from + 3 to +1 in a short time. In my case, how soon the tension fell I cannot say, as Dr. Shorter could not make an examination until the tenth day; it had then fallen from 2 to normal. In cases where vision is not entirely lost, improvement is gradual. Mohr reports improvement from $^{5}/_{15}$ to $^{5}/_{9}$, with an extension of the field of vision from 5 to 10 degrees; Abadie saw vision increase after several months from $^{1}/_{10}$ to ⅓ on the left and ½ to ⅔ on the right.[7]

In Europe the operation has been performed in glaucoma more than thirty times by Abadie, Jonnesco, Chipault, Zimmerman, Demercheri, Mohr, and others, with almost unvarying success, and it has become one of the established operations abroad. Cases are reported of relief lasting up to the third and fourth years after operation. In America the operation has not become so popular. J. M. Ball in a personal letter states that he can learn of only three other surgeons on this side who have performed sympathectomy for glaucoma, G. F. Suker, of Toledo, D. H. Coover, of Denver, and A. R. Kiefer, of St. Louis. Each of these has done one successful operation. Dr. Ball has himself operated five times, four times for glaucoma and once in atrophy of the optic nerve. Since his paper was read at the International Ophthalmological Congress at Utrecht, and published in the *Journal of the American Medical Association* last June, he writes he has operated once for hemorrhagic glaucoma in a young man aged twenty-five years, left eye completely blind, tension + 2, pupil widely dilated, the ophthalmoscope showing numerous hemorrhages and cupped disc, heavy continuous pain in and around the diseased eye. He had been advised to have enucleation performed for relief of the pain. Dr. Ball performed resection; one year later the eye is quiet, entirely free from pain, and tension is normal. Had sympathectomy been performed before vision was lost, he believes that the sight would have been improved. Abadie, he states, reports a similar case operated on in the earlier stages with good visual results. From his study of glaucoma, Dr. Ball is led to believe that the disease is an effect of pathological changes in the sympathetic nervous system, resulting in microscopical changes in the nerve tissue of the superior cervical ganglion. He has kindly loaned me some drawings of sections of a normal ganglion and of excised ganglia removed for glaucoma, illustrating these pathological changes in the ganglia fully justifying the facts of his claim. As these drawings are to appear in his book on ophthalmology, I have taken the liberty of having copies made and present them in this connection. Prof. Ball has the honor of being the first American operator to perform sympathectomy, and also of being the first to operate in atrophy of the optic nerve.

Fig. 1.

Microscopical appearance of a normal sympathetic ganglion. (Kindness of Dr. Ball.)

Sympathectomy is indicated in glaucoma simplex, inflammatory glaucoma where iridectomy has failed, hemorrhagic glaucoma early in the disease; and it should be tried in absolute glaucoma with pain, in preference to enucleation. In unilateral trouble the ganglion of the corresponding side should be excised. While sympathectomy may not be curative in

every case of glaucoma, the results thus far have been sufficiently satisfactory to make it a desirable procedure in this much dreaded disease.

Bilateral removal of the three cervical ganglia in exophthalmic goiter is followed by relief of precordial pain, decrease of the pulse-rate and retraction of the balls of the eyes, but as far as I can learn, there is little or no early diminution of the goiter following the operation. Little is definitely known of the physiological action of the middle ganglion; its branches to the thyroid gland are supposed, however, to control its secretory activity and its nutrition. If this is true, resection of the ganglion should produce some demonstrable action upon the thyroid circulation, change its size, or paralyze its secretions; simple section fails to show any results whatever, while removal of both the superior and middle ganglia

Fig. 2.

Microscopical appearance of a sympathetic ganglion removed for glaucoma. (Kindness of Dr. Ball.)
1, artery; 2, vein; 3, area of small round-cell infiltration; 4, round nerve cell; 5, connective tissue; 6, atrophied nerve cell.

alone has been abandoned as useless and incomplete in disease. Wertheimer believes that certain fibers of the sympathetic chain in the neck do control the secretory functions of the thyroid. This is doubtful, since it is stated by some operators that resection has no effect on the colloid matter secreted in the gland, as the goiter does not usually decrease in size. Combermale and Gaudier,[7] agreeing with Wertheimer, believe that after section of the main trunk the thyroid fibers cease to preside over the thyroid secretion; this secretion in the disease under consideration, being a toxin, causes the tachycardia. The drop in the pulse-rate, which is delayed, they think is due to the stoppage of the toxin secreted, for if it was due to the simple section of the nerve supply to the heart, retarded action should come on immediately. Dr. Inglis[8] entertains the theory that the group of symptoms found in exophthalmic goiter is due to the entrance into the blood of altered thyroid secretion. The normal secretion, he says, is an enzyme, affecting the tissue growth; in this disease the secretion is a poison having elective action on the nervous system, particularly the sympathetic. Possibly Dr. Inglis has mistaken the result of sympathetic nerve change for its cause. In this connection, I would suggest that possibly Dr. Ball's experience in finding microscopical changes in the superior ganglion in glaucoma cases may be true also of all the ganglia in Graves' disease; if so, these nerve changes may so affect the functional action of the thyroid that toxin secretion would be excited. Further, it is claimed that sympathectomy meets with its best results in primary exophthalmic goiter; those cases in which the tachycardia precedes the enlargement of the gland, and in which thyroidectomy is most fatal. If Dr. Ball's theory of the possible dependence of glaucoma on disease of the sympathetic system, in which microscopical nerve changes appear, is true, is it not possible that the good results of the operation in primary Graves' disease are alike dependent upon the removal of a diseased chain of ganglia which affect the eyes, the thyroid and the heart through a toxin secretion of the thyroid gland? In secondary exophthalmic goiter the operation is less favorable; here the rapid pulse and exophthalmos come on after the goiter and are dependent upon its pressure on the vagus (Jonnesco). Thyroidectomy in this condition gives better results.

Jaboulay deserves the credit of introducing sympathectomy for Graves' disease, as he first advised the operation, and on September 2, 1895, made the first deliberate section of the cervical sympathetic. Combermale and Gaudier report a case in which there was early diminution of the exophthalmos, immediate disappearance of precordial pain and a reduction of the pulse from 200 to 100 during the first week, but no modification of the goiter itself. Jonnesco reports immediate disappearance of the exophthalmos, relief of nervous symptoms referable to the heart, diminution of the trembling, tachycardia, carotid pulsation and thyroid thrill when present, and in one case a fall in the pulse from 140 to 70 and 80. In fifteen cases he has had 60 per cent. cured and 40 per cent. improved; one case he reports of unilateral operation with improvement of the corresponding side. Chipault reports six cases cured. Other European operators have had equally good results.

In America I can find only one surgeon who has performed sympathectomy in exophthalmic goiter. Learning from Dr. Hartwig (personal communication) that Dr. B. Farquhar Curtis, of New York, had once operated, I wrote to Dr. Curtis, and with his kind permission, I present the notes of his case, which has never been formally published:

"Woman, Irish, twenty-nine years old, residence New York City, married; for two years she had had symptoms of exophthalmic goiter; admitted to Dr. Curtis' service, Bellevue Hospital, May 12, 1899. Moderate exophthalmos; considerable nervousness. Thyroid gland much enlarged, estimated size of hen's-egg on each side. Paralysis of right vocal cord. Pulse not very rapid—106 the highest. Medical treatment tried and failed during two years.

"Operation May 17, 1899. Ether anesthesia. Cervical sympathetic removed (1st and 2d ganglia and cord down to the 3d), bilateral section. Wound sutured. Primary union. No effect on pupils. Gradual improvement in nervousness and exophthalmos. Thyroid reduced in size. Paralysis vocal cord cured. Ten months later, she was presented to the Neurological Society; the improvement had continued in all symptoms except the pulse. *This was more rapid and a cardiac murmur could be heard.*" (Italics are mine.)

Dr. Curtis closes his letter with the remark that the cardiac complications in the case may be of independent origin, but that the case is one which can be classed as a decided improvement, in which I fully agree. He further says that this is the only case in which sympathectomy for exophthalmic goiter has been performed, that he knows of, in the United States. The results in Dr. Curtis' case are certainly sufficiently gratifying to encourage other American operators to follow his lead in this distressing disease. The results of resection of the sympathetic for this disease have been universally favorable, and thus far the operation has been without danger. Such being the case, total bilateral resection, although a delicate operation, is certainly superior to thyroidectomy, which is extremely hazardous, and it should be undertaken in all primary exophthalmic-goiter cases in which medical treatment has failed.

Jonnesco, basing his perseverant advocacy of the operation in epilepsy on the idea that the disease is due to a cerebral anemia, believes that complete bilateral resection of the cervical sympathetic so alters the cerebrospinal circulation that hyperemia takes the place of ischemia. Increased nutrition to the nerve-cells is thereby supplied and the toxic products of disease are rapidly eliminated. Beginning in 1896 he has up to August of the present year made 126 resections; 97 of these operations have been undertaken for epilepsy. To him, certainly, belongs the honor of doing the first complete bilateral sympathectomy, and also the credit of persistently developing its various indications. He was not, however, the originator of the operation, not even for epilepsy. Alexander of Edinburgh is credited with having performed resection of the cervical sympathetic as early as 1889; Jacksh, Baracz and Bojdanick operated in 1892 and 1893; while Jaboulay advised the operation in epilepsy in 1895. The rationale of the cure of epilepsy by sympathectomy is much less substantial than is the theory of the relief of glaucoma and exophthalmic goiter by the same procedure, while the results are far less encouraging. Jaboulay and Lanois,[10] in a study of the subject, expressed themselves as doubtful of the advisability of the treatment, having noticed that in those cases which were improved, and more especially in those cases which were cured, there was a strong hysterical element in the histories. Le Borde advises that it should be abandoned as a remedy for epilepsy. Chipault reports in August, 1900, three cases cured and twenty uncertain in results. Schober, on the contrary, in 1899, showed that not a single case had been cured in all of the operations in Paris. Carl Beck, after reporting three cases[11] comes to the conclusion that the operation has no value in epilepsy. In one other American operation, by Dr. Ed. J. Meyer and Dr. Hartwig (personal communication), as far as I can learn the result is doubtful. Even Jonnesco's latest statistics,[12] embracing his entire 97 cases, show only 12 cases cured, 7 improved, and 11 unimproved; while 45 cases, he stated, had disappeared or their results were unknown (?). Five of his cases died, not immediately, but soon after, of other complications. Still Jonnesco enthusiastically continues to operate; even extending, in his last four cases, the operation so as to embrace the thoracic ganglion. From these facts it would seem that sympathectomy in epilepsy must finally be abandoned, just as ligature of the vertebral arteries has been given over as useless if not harmful.

The physiologists claim that resection of the cervical sympathetic in animals subjected to experiment is followed by permanent trophic changes and atrophy of the brain. As yet no such results have been noted in man. The operation is still too new, only four years old, to demonstrate what ultimate deterioration may result. Thus far, however, the beneficial results have remained permanent and unless some remote baneful effects should be reported to detract from the value of the operation, sympathectomy will eventually receive a permanently recognized position as a surgical procedure in glaucoma, exophthalmic goiter, and other allied neuropathic diseases.

In this study I am largely indebted to the kindnesses of Dr. James Moore Ball of St. Louis, Dr. M. Hartwig of Buffalo, and Dr. B. Farquhar Curtis of New York for much valuable suggestion, information and material given by personal letters and clinical matter forwarded to me.

THE QUESTION OF DRAINAGE IN APPENDICITIS.

BY A. M. POND, M.D.,
OF WEBSTER CITY, IOWA.

Nearly every point of technic in the operation for appendicitis has, in the recent past received its full share of comment from men who have possessed liberal educations, broad clinical experiences and with records of merit in their labors. The past few months, however, has witnessed so many radical changes regarding the treatment of the wound that I take the liberty of attempting at this time to view the subject from the standpoint of drainage, or more properly speaking non-drainage.

Much of our knowledge concerning abdominal drainage we owe to the labors of the gynecologists; they recognized the fact that when abscess cavities were ruptured intraperitoneally that little or no harm came of it, providing it was *not* walled away from the rest of the abdominal cavity and that the septic material could be presented to a larger portion of the peritoneum. Septic areas in their field were cleansed with as much care as possible and the abdomen thoroughly irrigated and closed with good results. These patients showed a decrease of hernias and resulting ileus following operation and presented an earlier and firmer union, and a more tranquil convalescence, than when the cavity was drained.

About this time, general surgeons held that many of these gynecologic conditions were cases in which the pus was sterile, hence, the peritoneum was able to dispose of it without serious results; in time, however, it was shown by experiment, as well as in practice, that the peritoneum was capable, and did dispose of large amounts of specific pus, pus proven by examination to contain the staphylococcus, streptococcus and bacillus coli communis organisms, which for the most part are present in many cases of abdominal surgery.

It is an open question still whether it is the drainage or the peritoneum that takes care of the larger amount of septic material; when the fact of rapid formation of pus is considered, it is hardly possible to believe that it is all removed by drainage, for capillary attraction, the physical force to which drainage owes its application, is at best a slow process and if the peritoneum does not take care of that which is not removed by the drain, how can we explain its removal; again, granting that the gauze removes all the pus, how does the peritoneum tolerate the presence of pus that must accumulate at the bottom of the drain, during this drainage process, if it be so susceptible to infection?

That this pus is produced very rapidly cannot be denied, else we would not have the fulminating types of appendicitis. All of the authorities recognize this fact when they urge an early operation. Who has not noticed in using the glass drainage-tube how frequently pus can be drawn from it in surprisingly large quantities. All this goes to prove the inefficiency of our attempts at drainage, and not only this, but the mere presence of the drain is productive of much harm; it unquestionably produces a hyperemia and congestion of the peritoneum in closest proximity, thereby lessening the absorption by disturbing its normal currents, it also produces adhesions about the drain which in turn lessens the area of the peritoneum exposed to the infection, thereby limiting its important function of absorption.

It is believed that so long as the gauze or tube is sterile, little or no harm can come from its presence; this is erroneous; the peritoneum will tolerate no foreign body, sterile or otherwise, without a disturbance of its function, besides interfering materially with its healing.

It is known that the peritoneum is capable of disposing of large quantities of pus under favorable conditions, and chief among these conditions is equal distribution over the peritoneal area; in order to do this it becomes necessary to use some agent which will put pus and pus-forming elements into solution, and in choosing this agent some very important points to be desired may be mentioned.

1. Sterility. One species of bacteria is often inert or latent until another species is introduced, thus combining the efforts of both, and a heretofore latent sepsis becomes a rapidly active infection.

2. Power of holding in a homogeneous solution the pus as well as the blood and blood-clots incident to the operation, in order to permit of equal distribution over the peritoneal cavity. The presence of blood-clots in a septic cavity cannot be overestimated; no richer culture medium is known for bacteria and these must be protected from invasion.

3. Stimulation of absorption. It is most desirable to remove all septic material as soon as possible and this is made possible by the power of absorption of the peritoneum which is enormous, namely, from 3 to 8 per cent. of the body weight in one hour.

Hot saline solution is very effective and fulfils all the requirements; it can be made sterile and introduced sterile into the peritoneal cavity; it possesses the power of putting pus and pus-forming elements, such as blood and blood-clots into solution, thus removing the danger of fresh invasion of infection, and being hot, temperature 105° to 108° F., is a most active stimulant to the peritoneum and its use is unattended by unpleasant sequelæ.

Increased hepatic activity is another step in the right direction. Such activity produces a detergent influence in all cases of general

sepsis as well as in localized infectious processes, besides removing from the entire physical economy various substances which in themselves would aid, if not produce, septic conditions; this function is certainly worthy of careful study, as it will increase the resources of the surgeon in combating infection, since through the portal circulation we can increase the general resistance against bacteria.

Posture does much in these cases; elevation of the foot of the bed a few inches tends to gravitate the fluids toward the diaphragm and absorption is increased in this locality since the diaphragmatic lymph-spaces afford an avenue of rapid absorption of sepsis held in solution.

I herewith take the liberty to report some cases where these ideas were put in practice.

Case I.—Mrs. M., age thirty-two years; history of attacks of recurrent appendicular pain for over a year, lasting a few days and subsiding; last attack had continued for four days; tumor well defined; temperature 101.4° F., pulse 120 and threatening.

Incision was made parallel to Poupart's ligament and about 1 or 1½ inches internal to it; as the subperitoneal fat was reached, it was found to be edematous and oozed freely on incision; the peritoneal cavity was opened and the appendix appeared in the wound without search and was fully four inches long, with a peri-appendicular abscess containing about two ounces of foul pus; the appendix was removed and the stump penetrated with a probe to remove all doubt of constriction, then treated with pure carbolic acid, inverted and there secured with a purse-string suture of fine catgut. The canal of the amputated appendix showed plainly the evidences of previous inflammation by a constriction, below which was a small abscess. The entire peritoneal cavity was then thoroughly flushed with hot sterile salt solution, while a gloved hand searched the abdomen for more abscesses; none being found the fluid was gently pressed out and the cavity wiped with sterile gauze, then filled again with the hot saline solution and the wound closed by through-and-through sutures of silkworm gut, the wound was then thoroughly washed with hydrogen dioxide and dusted with a powder of iodoform and boric acid (1 to 7); sterile gauze was then applied, and a sterile bandage held all in place.

Just before coming from the table the patient was given a high rectal enema of a quart of the hot saline solution and put into a bed with the foot elevated about four inches. That night she suffered from some nausea and gas and pains incident to the operation, and next morning she had a temperature of 100.2° F., pulse of 96; an ounce of hot solution of sulphate of magnesia was ordered and about noon that day the bowels were moved freely. The stool was brown in color and liquid. Evening temperature was 99.6° F., pulse 90; the following morning found a normal temperature, pulse 82 where it remained; on the tenth day the stitches were removed and the wound was found completely closed, the scar was washed with alcohol followed with sterile water, on the twelfth day she sat up and on the fourteenth day was dressed, and has since gone on to a very satisfactory recovery.

Case II.—Laborer, German, age twenty-eight years, no history was obtainable. He was found in a moribund condition; blood-count revealed a high leucocytosis—28,000. There was an evident tumor, rigid abdominal wall. Incision was made in the same line as described. Rapidly reaching the colon, the appendix was found adherent behind the cecum. In delivering it into the wound a pus cavity was broken which discharged a large quantity of thick pus. The appendix was ruptured and contained a small concretion, the size of a small pea. After it was amputated the canal of the stump was found to be pervious, and it was treated in the manner of the previous case. The cavity was then thoroughly irrigated while the gloved hand made search. An abscess was found in the region of the liver; this was broken down and freely flushed with the hot salt solution, the tip of the tube being carried near the site. The cavity was then emptied and dried with a gauze sponge, after which it was filled with the hot solution and closed. This was followed by a high rectal enema, an ounce of sulphate of magnesia in hot water was then ordered to be given as soon as consciousness was restored. Evening temperature 100.3° F., pulse 96; next morning the temperature was 102° F., and the pulse 110. After the evacuation of the bowels occurred, there was a declining temperature and a falling of pulse; stitches were removed the tenth day, and convalescence was uneventful and complete.

Case III.—L. S., age thirty-two years, teamster, gave history of recurrent pain in right groin. Onset was sudden, nausea and vomiting, temperature 101° F., pulse 120 in the forenoon, evening temperature 103° F., pulse 132.

Operation next morning, tumor well marked, abdomen rigid. On entering the peritoneal cavity a large amount of pus was evacuated and an abscess was found walled away from the entire cavity; adjacent coils of intestines were massed by the adhesions of plastic exudate; appendix was found in fragments in the abscess cavity; stump was amputated and treated with carbolic acid, inverted and held by fine catgut. The cavity was then thoroughly flushed and after drying, the intestines were carefully freed of adhesions and while it was impossible to remove all the adhesions, care was taken to leave no bands that could afterward cause trouble by entrapping coils of intestines and produce ileus. After the adhesions were freed the abdomen was again filled with the solution and was searched for

abscesses. None being found the wound was closed with as much hot salt solution as could be retained; the high enema was then given. On the second day after operation the temperature rose to 102.6° F., and pulse to 120, but subsided at night and on third day the temperature was 98.6° F., and pulse 86; the stitches were removed at the usual time, and while recovery was slower than in the preceding cases, it was uneventful and complete.

Case IV.—H. W., age twenty-four years, an electric lineman, gave previous history of pain in the right groin for about one year. Nausea and vomiting were present, intense pain, no tumor evident, abdomen rigid, temperature 102.4° F., pulse 128.

Incision was made in the same site as in previous cases; the appendix was found to be gangrenous at tip and completely sloughed away from the cecum, being held in place by the meso-appendix. A pus cavity was ruptured in delivering the appendix; slight adhesions to colon behind were found. As the appendix was lifted up and cut away, it slipped from the grasp of the tissue forceps, striking on the internal lip of the wound at about the center of its extent. The abdomen was then treated as has been described by flushing the cavity while search was made, this was then emptied and again filled and closed retaining the salt solution. The history was much the same as in the preceding cases until the seventh day when there occurred a sudden rise in temperature from normal to 102.4° F., rapid pulse 134, bowels were confined, appetite poor, and there was a feeling of general indisposition. The dressings were removed, and the wound inspected. About the middle of the incision on the internal side a slight oozing of pus was discovered, the suture near it was cut and removed and perhaps an ounce of pus escaped from a mural abscess. This was irrigated with hot saline solution and redressed daily until the tenth day, when all the stitches were removed; at that time the small abscess was completely healed, and the patient was able to be about the street in three weeks from the day of operation.

It may be merely a circumstance, but it is possible that the infection of that wound could have occurred by the amputated appendix striking the edge of the wound in its fall, for the site was identical.

Case V.—R. H., male, age eleven years, temperature 102° F., pulse 120, abdomen rigid and tumor evident.

Incision made over tumor. On entering the abdomen, a large amount of pus escaped. The appendix was found very much enlarged and elongated, with perforation and contained a very large concretion. It was amputated and stump treated as in previous cases. The abdomen was then irrigated with the hot solution. During the search another abscess was found in the left iliac fossa; the tip of the tube was carried to the site and thoroughly flushed, this was then wiped away, and the abdomen filled and closed. After the stitches were tied and the wound treated with hydrogen dioxide, it was discovered that a large gauze pad was missing, search about the room failed to reveal it, the abdomen was reopened and the pad found and removed. As the patient was in very bad condition, the stitches were replaced very hurriedly, the high enema was given as usual, the patient put to bed. On the second day the temperature was 101° F., pulse 130, but both subsided at night on the third day, the temperature was normal and the pulse 86. On the eighth day there was a decided chill, followed by a sudden rise in temperature to 102.3° F. The dressings were removed, a large mural abscess was found, which was irrigated and packed with gauze and dressed daily. On the fourteenth day all stitches were removed, on the twenty-first day the wound was completely healed and recovery was complete.

Case VI.—C. C., male, student, age fourteen years. Was seen at first complaining of pain in right groin, nausea and vomiting, temperature 99° F., pulse 120; next evening temperature 100° F., pulse 130.

Operation performed the following day. The appendix was found to be very much elongated and hyperemic, no pus was found, no concretion present. On section of appendix a small amount of pus escaped. The salt solution was used as already described, and the abdomen searched with negative results and was then closed full of the solution and dressed in the regular manner. The temperature for two days was 99° F., and pulse gradually declined from 96 to 84; after the third day the temperature reached normal, pulse 84, where it remained. On the tenth day all stitches were removed and on fourteenth day the patient was dressed; recovery complete.

In each of the above cases the tube of the irrigating bag was rendered sterile by carbolic and bichloride solutions so that it might be carried anywhere in the abdominal cavity and thorough flushing of any septic area could be performed; during this process the gloved hand searched the abdomen for localized areas of infection and it might be well to remember that the region of the liver, the left iliac fossa, the fossa between the rectum and the bladder, and the right iliac fossa are common sites for such abscesses.

The hand makes the solution of sepsis more certain since any and all regions may be palpated, and if this is done systematically and each region of the peritoneal cavity thoroughly explored before moving to another, complete solution may be assured and the safety of the proceeding unquestioned. After the search is complete the fluid is gently pressed out and in doing so it floats the flocular material and by removing this lessens the danger of active

processes. If localized infection has been found the region is carefully mopped out with a sterile gauze pad, and the tube replaced in the wound and the abdomen closed as full of the fluid as can be retained.

Whenever practicable two drams of the aromatic fluid extract of cascara was given before operation, followed by an ounce of magnesium sulphate in hot solution as soon as consciousness was regained; this procedure lessens the danger of intestinal paresis by stimulating peristalsis, besides increasing absorption. The foot of the bed was elevated about four inches during the first twelve or eighteen hours.

In reviewing these cases it is at once apparent that where the technic was unquestioned the results were most satisfactory; in Case IV. the infection undoubtedly occurred by the amputated appendix striking the edge of the wound in its fall; this infection did not take place in the peritoneal cavity; it was a mural abscess and yielded readily to treatment.

In Case V. I think that infection occurred during the second suturing, as a result of faulty technic, as the sutures were placed very hurriedly, time being an element to be seriously considered.

While these cases may not appeal to many to be of statistical value it must be granted that they prove what can be done without drainage in appendicitis. It seems that the general trend of the times is to do without drainage in all classes of surgery, as far as the removal of pus is concerned, drainage must be used in surgery of certain glands, ducts, and cysts in order to remove the irritating fluids that would interfere with the processes of healing, as in cases of surgery involving the stomach, spleen, pancreas, liver, gall-bladder, and urinary bladder. The maxim given with so much wisdom a few years ago, "When in doubt, drain" is about to be revised to read "When in doubt, do not drain."

NEW METHODS IN CHARITY, WITH BETTER RESULTS AND AT LESS COST.

BY WM. P. SPRATLING, M.D.,
OF SONYEA, N. Y.;
MEDICAL SUPERINTENDENT, CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.

When the Hon. James A. Roberts was State Comptroller, in 1896, he wrote some true, pungent and striking things—things that ought to engage the attention of charity workers throughout the State concerning the cost, the *ever-increasing* cost, of the public charities of this great State. In his report for 1896, Mr. Roberts says: "The State now has invested the sum of $19,323,245.42 in the way of buildings and permanent improvements for the defective and dependent classes; classes that must *always* be cared for by the State." It costs the State $5,200,000 annually to care for this immense army. The bulk of this, fully three-quarters of it, goes to care for the 20,000 insane.

The foregoing figures have increased since then; but I use them partly because they are less astounding, and because they are the latest I was able to secure that gave the information I desired in a specific and definite manner.

Pray understand at the outset that I am not opposed to State charities—indeed, far from it; but if better means can be devised at less cost, then I am firmly in favor of such better means at less cost. The question is: Can we care for the State's great army of the defective and dependent classes without lessening the value of the care they now receive, and do it at less cost? I ardently believe it can be done, and I will try, in the briefest manner possible, to tell you how. The means to be adopted come under the following heads: (1) Prevention; (2) Construction; (3) Maintenance; (4) Proper Education.

Prevention, of course, means placing legal restrictions upon the increase of the defective and dependent classes. That the State, or the government under which we live, has the right to do this, there should not be the shadow of a doubt. Just as society has the right to protect itself against any invading foe that threatens the fabric of its social organism, by organizing the equipping armies and by doing what fighting must be done, so it has the same right to make laws, and enforce them, that will cut off or prohibit the ever-increasing army of defective and dependent people that must in time be cared for at the expense of the State. These opinions are self-sufficient to sustain the point.

The next step is to appoint a commission, the aim of which will be to frame laws designed to correct this growing evil. This commission must needs go slowly; it must not make any more mistakes than possible; it must not bring down upon its head the wrath of a whole people by drafting measures too drastic at the outset. It is harder, I know, to go upward and forward than it is to go downward and backward. Let progress be steady, but sure; otherwise defeat of the entire scheme would be invited at the outset. Some States, I believe, have enacted laws to prevent the marriage and intermarriage of epileptics.

The first thing, therefore, is prevention, and the first thing to be done to carry out prevention is to prohibit the marriage and intermarriage of defective, dependent and diseased people, people whose progeny, once created, are bound, in the course of human events, to become public charges. We see bacteriologists throughout the world toiling incessantly to devise means to prohibit the origin and the spread of communicable diseases, and I could give you a long list of men who are spending the better years of their lives in the study of means to prevent one disease only, such as tuberculosis, or yellow fever, or some disease of that kind. Why cannot we, who devote our lives to the care of those mentally-stunted, ineffective, blind, and nothing but dregs of society, do something toward stopping their

production? Let us check, as well as maintain; prevent, as well as cure. Let us begin at once. Let us appoint a commission to take up this matter and drive it home. Action, intense action, vigorous and everlasting action, is the only thing that is demanded. Set that at work, keep it going, and, rightly going, you are bound in time to gain the point.

Construction is the second point I would bring up. I do not quibble over terms, nor fear to express conditions of the past. I have no hesitancy in saying that nine-tenths of the great public charitable institutions of this State that have been built in the past have been built in the form of great, towering, massive structures, more to satisfy a local pride than to create a suitable home for those for whom they were devised. This is all wrong. For the life of me I cannot understand why a person of feeble mind, or an idiot, or an epileptic should require a home one bit more colossal than that occupied by the ordinary, well-to-do artisan or tiller of the soil. The argument is used that "This building is for the State, and the State builds for keeps." So do others, who are thrifty and wise. The State should not build cheap or shabby structures, but it should build simple, well-constructed homes. In five years' experience at the Craig Colony for Epileptics, I have come to know that suitable homes can be built for a vast majority of the State's wards at a cost not exceeding $400.00 a bed; indeed, under suitable conditions, I am satisfied this might be further decreased. We are housing today, at the Craig Colony for Epileptics, 612 epileptics in buildings none of which cost over $450 a bed, and more than one-half of which cost less than $400 a bed. Nor have we built poorly, for we have built well. We have founded our buildings upon a rock, and I am satisfied they will endure for a century. Could you ask for more?

If the State has more than $19,000,000 invested in permanent buildings, and if it could reduce the cost of construction one-third, and if it is expending from $1,000,000 to $1,500,000 a year for new construction, it could save at least $400,000 a year in new construction—which sum will go a long way towards maintaining those persons already under State care—by building simpler homes for these people. It is what they have been accustomed to that we wish to give them; it is what their condition demands, and there is no valid reason why any of them should live in expensive structures, costing anywhere from $1,000 to $3,000 a bed.

Maintenance is the third question to be considered. A great bugaboo, an unnecessary bugaboo, of great proportions and tremendous possibilities, has been raised over *per capita* cost. The result has been competition on the parts of the various superintendents and managers of the great public institutions to bring down their *per capita* cost lower than the *per capita* cost of some other institution. This is all wrong—disastrously so; let the charitable institutions spend what they need for proper and legitimate purposes; let them spend *more money* on the care of the *acutely insane* and *less money* on the *chronic insane*. This applies likewise to all the charities of the State. We have not yet learned to classify properly; or, if we have learned, we do not put our knowledge into practice.

It is time that we begin. Let us separate the *absolutely incurable* and the *hopeless* cases from those that may be cured. Take the insane, for instance. I made a canvass of the 21,000 insane in this State last May and found, according to data given me by several enlightened superintendents, that fully 5,000 of the chronic insane living in the great State hospitals to-day could be colonized in small agricultural buildings on a vast tract of land, where far less money need be spent on their care. These superintendents were heartily in favor of the scheme.

I would advocate the colonizing of 4,000 or 5,000 of the chronic insane in one vast colony; or two, if it is thought best. Build for them cheap, simple, but good and substantial homes. Organize these places just as the State hospitals are organized. Give them a superintendent, a good corps of physicians, nurses and attendants, and stint them in nothing needed for the comfort and welfare of their charges. Make these colonies hives of industry and activity. Instead of the *per capita* cost of this number being $180 or more a year, I am confident it could be brought down in time to $100 a year, or less. Then take from the difference some of the amount saved and build in connection with the great cities, or centers of population, like New York, Albany, Syracuse, Rochester and Buffalo, psychopathic hospitals or reception hospitals—give it any name you choose, so long as you rob it of any designation that would make people feel that it is a place where lunatics are kept. Put into this building the best scientific brains that money can buy; equip it with the best surgical and scientific instruments, and all instruments of study, investigation and precision that man has invented. Provide it with the best possible nurses; in fact, leave nothing undone that will tend to bring about recovery in curable cases.

Do not make these special hospitals too large; make them small; so small that, with a proper hospital corps, each man will retain his identity, not be merely a member. For New York build, say, for 300 patients; for Albany, 100; for Rochester, the same; for Buffalo, 150. Let the acute and curable cases be sent there first for a year, or a year and a half; but let the period be elastic, not fixed. If they do not recover, then transfer them to the present existing great hospitals. Another advantage would accrue from the construction of these buildings in the great centers of population. Physicians, who are graduated by the hundreds in all the great cities where there are medical schools, could use these patients as object lessons, as clinical material. The result would be that the young physician who goes out into practice would have a far better

knowledge of diseases of the mind than the majority of them have to-day. This would aid vastly in the early treatment of diseases of the mind.

This is how I would treat the matter of maintenance. *Less money* for one-fourth of the insane, and *more money* for a certain per cent. of the acutely insane, with the idea of curing these at the very outset, if possible. I believe that the teaching of pathology should be done in connection with these hospitals for acute cases. I believe all the scientific work done in connection with the insane should be done in these hospitals, and that as many young physicians as possible should have the advantage of the hospitals. Build in connection with them dormitories in which physicians might live, so that they might be intimately in contact all the time with their difficult and important work.

Education is the next problem. The word *custody* is a most disastrous term applied to the charity wards of the State. It should never have been applied; it is now time to abolish it. Let us say that the charity wards of the State are under treatment, not under custodial care. For many of the insane, for many more of the epileptics—we have 100 of them at the Colony to-day out of 600, for many of the teachable idiots, and for most of the feeble-minded, we need a better system of education; an education that tends to put into the finger-tips of the individual taught a form of education that the individual can use in the acquisition of his daily bread. It is little less than absurd to attempt to force a $5,000 education into a $500 brain; it shows a lack of judgment on the part of those who are doing it, and it results in practically nothing. The State should pay more for good teachers, and an army of teachers should be created over and above that in existence at the present time. To me, it is a pitiable and depressing sight to go through many of the great State institutions and see its charges lined up in long rows down the sumptuously-furnished corridors, with folded hands and all idle; very few, if any, of them at work, and those who are at work are largely improperly employed under unskilled tutorship. The proper education of those of the State charges who should be taught would go far, I am satisfied, toward further reducing the *per capita* cost.

To sum up, then, I would recommend the following:

1. Prevent insanity, epilepsy, imbecility, idiocy and feeble-mindedness, as far as possible, by making it impossible for persons so afflicted to marry.

2. Build less expensive structures in which defective and dependent State charges shall live.

3. Maintain at less cost the cases that are chronic and incurable, and maintain at greater cost, to stimulate recovery, those that probably can be cured.

4. Give those that ought to have it an education that they can use, either in the institution that cares for them, that the cost of their maintenance may be lessened, or in the outer world, when they leave the institution, after the State has done its work well and turned them back into the great business current, as nearly normal men and women as science and art can recreate them.

MEDICAL PROGRESS.

Pendulous Abdomen.—L. Peters (*Annals of Surgery*, Mch., 1901) states that surgical removal of redundant abdominal fat when it causes symptoms amounting practically to those of a benign neoplasm is justifiable. He reports a case for Dr. H. A. Kelly of a woman who several years ago had fatty breasts taken away aggregating twenty-five pounds in weight. Dr. Kelly recently ablated a large segment of her abdominal fat which weighed nearly seventeen pounds. The result was satisfactory.

Treatment of Lead-Poisoning by Electricity.—J. Auriol Armitage (*Birmingham Med. Rev.*, Feb., 1901) has obtained thirty-seven cures, either partial or complete, in forty cases of severe chronic lead-poisoning, with paralyses, by the use of electrical baths. The apparatus used consisted of an ordinary large porcelain bathtub carefully insulated, special care being taken to insulate the inflow and outflow pipes. A large carbon at the foot of the tub formed the negative electrode. A small carbon, wrapped in linen rag and movable was used as the positive electrode. The battery he used chiefly was one of 120 large Leclanché cells coupled up in threes, and when freshly charged giving an electromotive force of about 60 volts. As the commencement of treatment from 84 to 120 cells were required to produce the desired effect, but at its close from 24 to 60 cells gave the same result. The feelings of the patient were the guide to the strength of the current. The best results were obtained when the current reddened the skin without causing actual pain. The patients were usually immersed in the bipolar bath for fifteen or twenty minutes. Armitage also used the monopolar bath, the carbon in the tub being the negative pole, while the positive pole was a brass bar laid across the tub outside of the water and grasped by the patient. The treatment was not complicated by the use of drugs, especially potassium iodide. The water, at a temperature of 98° F., covered the patient except his head. In the monopolar bath a greyish deposit was noticed on the brass rod after the bath. This proved to be lead which the writer thinks came off the patient's hands and not out of his system. In addition to the general bath the affected parts of the body received special treatment by being rubbed with the positive electrode. Armitage thinks that the rapid improvement obtained in these lead-poisoning cases was due to the electricity splitting up

the lead salts in the body, so that the lead formed new combinations, insoluble and stable. He reports in detail a number of cases showing the rapid improvement produced by these electric baths.

Hydro-Salpingitic Torsions.—F. Cathelin (*Revue de Chirurgie,* Feb. 10, 1901) states the symptomatology of torsions of the pedicle in hydro-salpingitis in the following terms: The prodromata are usually: pain of dull character, recurring in irregular crises, situated in the pelvis or either iliac fossa, radiating into the loins and lower extremities; regular normal undisturbed menstruation; hemorrhage, as a rare accompaniment of the pain-crises; leucorrhea as the sign of uterine congestion; tumor palpable to the patient or evident by its pressure symptoms. Acute torsion shows: pain lightning, horrible, violent and syncopal, in either side or general in the abdomen, excited by some definite exertion as a rule, controlled only by morphine hypodermatically, radiating usually downward and laterally; vomiting but never in the recorded cases, fecal; metrorrhagia, described by Pozzi as *"metrorragies distillantes"* not constant or reliable; intestinal obstruction, by paralysis, simulating the truly mechanical and often suggesting it; constipation as the rule; diarrhea as the exception; localized, usually aseptic peritonitis; feeble rapid pulse; fever exceptionally; facies of shock; usually distension, rarely retraction of the abdomen; exceedingly great sensitiveness to palpation; a tumor, if previously known much augmented, or if not previously unknown manifest to patient and examiner, due to venous obstruction, situate usually in the abdomen or superior strait or rarely in the pelvic cavity, elastic or fluctuating, usually non-adherent. The twisted pedicle is occasionally palpable (de Warnek's sign). The chronic cases in their paroxysms are like the acute and the history of recurrent crises supplies as a rule the diagnosis. Extirpation of the cyst and its pedicle is the treatment.

Varicocele.—W. H. Bennett (*Brit, Med.* Jour., Mch. 2, 1901) says that fatty degeneration of the testicle is due to the fact that in the usual operations all balance between the arterial and the venous currents is destroyed. In a series of two hundred cases he has had no such accidents while doing the operation so that not only the spermatic veins but also the spermatic artery is obliterated, while the veins and arteries of the vas deferens are left *in situ.* His procedure is to expose the cord with its envelope of fascia just below the external abdominal ring and then separate the vas deferens and its vessels from the whole of the rest of the cord and without denuding the vessels of the envelope of the fascia. Thus the veins and artery of the spermatic group are obliterated and no loss of balance occurs. The nutrition of the testis is carried on by the artery to the vas deferens and twigs from the tunica vaginalis to the testis. Aside from this special feature, all the other steps of the operation are the same as in the common open operation.

Treatment of Drug Habits.—David Paulson (*Medical Standard,* Mch., 1901) discusses the different methods of cure of these habits, such as the absolute withdrawal of the drug without supporting measures, the substitution method, the tapering off process, and the rapid withdrawal of the drug with physiological supporting measures. The treatment he has found most succesful is the following: The patient must have the attention of trained nurses, as he will need constant attention for the first few days. Not only must the morphine or cocaine be banished, but also liquor and tobacco or any other similar habit must be stopped. The diet should be such as is absorbed readily, and introduce nothing into the system that will tend to excite the already over-irritated nerves. Kumyss, butter-milk, hot malted nuts, and an abundance of fruit and fruit juices are well borne even when the patient is at his worst. Meat, and particularly beef-tea, aggravates the patient's condition. As the patient has usually taken a little more than the average dose before he puts himself under the physician's care, the nurse has little to do during the first twelve hours but watch the patient and see that he does not secure more of the drug. At the first appearance of restlessness, the nurse should take the patient in a wheelchair to the bath-room, and give him a neutral galvanic bath, with the water just at the temperature of the skin with a mild galvanic current passing through it. This is soothing and the patient can remain in it for an hour or more. The bath is followed by gentle massage, then by hot fomentations to the small of the back or wherever the patient feels pain. Then the patient's entire body is enveloped in a sheet wrung as dry as possible from water at a temperature of 80° F., and covered with enough blankets to produce a moderate reaction, but not perspiration. This is a very sedative measure. As soon as the patient begins to become uneasy this should be removed, and the patient wheeled back and forth in a wheel-chair. Then he may receive another neutral bath or a mild galvanic current to the spine. If the heart's action seems to be weakening, cold compresses are applied over the cardiac region, or alternate applications of hot and cold. If the patient is markedly prostrated one or two small doses of morphine may be given. For the diarrhea that comes with the withdrawal of the drug Paulson gives every two hours from the beginning large doses of the bismuth compounds with small doses of coto bark fluid extract. During the first thirty-six to forty-eight hours the patient has only secured snatches of sleep, but the struggle with the morphine is over.

He must have tonic treatment and a continuation of the neutral baths for some days, until he can get a good night's rest. His general system must be brought up to par by exercises, various hydriatic measures, and gradually increased diet. The patients are invariably cured after a few weeks of this treatment.

Saphenaresection.—P. Herz (*Deut. Zeitsch. f. Chir.*, Vol. 58, pt. 3 and 4) says that recurrence of the varices after the Trendelenburg saphenaresection are not uncommon. Therefore Habs has introduced a modification which appears to avoid these lapses. According to the arrangement of the collateral circulation beneath the skin one or more short transverse incisions are made joining the longitudinal incision. In this manner many of the collateral veins themselves varicose and productive of relapses are tied and ablated and the return flow determined though the deep intermuscular veins.

Leucemia and Pseudo-Leucemia.—In the *Inter. Med. Mag.*, Mch., 1901), C. H. Miner reports a case of typical leucemia and contrasts it with a case of so-called splenic anemia or pseudo-leucemia. The patient was a Pole, nineteen years of age, who was taken with severe pain in the left side in 1895 and his skin began to grow darker in color. Since then he has had several similar attacks of pain and his spleen has gradually been increasing in size till it extends seven inches below the free border. His skin has continued to grow darker, he has had frequent nosebleeds, with purpuric attacks, edema and hematuria. The blood examination has not varied much, there being about 2,500,000 red blood-cells, 4,000 to 8,000 leucocytes and a hemoglobin of 35 per cent. to 40 per cent. A differential leucocyte count showed: Polynuclears, 75 per cent.; small mononuclears, 16 per cent.; large mononuclears, 4 per cent.; transitionals, 3 per cent.; eosinophiles, 2 per cent. No malarial organisms, no nucleated red blood-cells or myelocytes were found. Osler says that it seems probable that in these cases the enlargement of the spleen and the anemia are both due to the same cause as yet unknown. It is better provisionally to group these cases of splenic enlargement with anemia, and without lymphatic involvement, under the name splenic anemia. The treatment is that of severe anemias. The spleen is sometimes removed in chronic cases with recurring hemorrhages.

Enlargement of the Phalanges.—As causes which may lead to thickening of the end-phalanges of the fingers A. Dennig (*Münch. med. Woch.*, Mch. 5, 1901) gives the following: (1) Disease which leads to purulent or gangrenous changes such as tuberculosis with cavity formation, bronchiectases, empyema, cystopyelonephritis and dysentery; (2) infectious diseases and chronic intoxications, such as pneumonia, pleurisy, lues and perhaps alcoholism; (3) cardiac disease, especially congential; (4) malignant tumors, and (5) diseases of the nervous system, such as syringomyelia and neuritis. A unique case which cannot be classified in above list was a man in whom pyloric stenosis following ulceration was found. Here the thickening entirely disappeared with the surgical cure of the disease. As a result of the examination of many cases with Röntgen rays the author believes that the hypertrophy is due solely to congestion and hyperplasia of the soft parts about the bone.

Ovarian Secretion.—According to S. W. Bandler (*Med. Rec.*, Mch. 16, 1901) there is a current in the peritoneal plasma which carries the freed ovum into one or other of the Fallopian tubes. Through the tube the ovum finds its way into the uterus in thirty hours. This ovulation does not cause menstruation, but is due to the same cause, namely a special ovarian secretion. If this secretion is diminished in amount, ovulation may take place without menstruation, or both may fail. The common causes of amenorrhea are atrophy, ill-development, or absence of uterus, chlorosis, lactation, and adiposity. In chlorosis the ovarian secretion is not sufficient to induce menstruation; during lactation the secretion is diverted to the breasts; and in adiposity the lack of secretion is a cause of the fatness, such girls being well-developed with fatty breasts, but with poorly-formed genitalia. An atrophied uterus tends to be accompanied by bodily weakness, both being due to a diverted ovarian secretion, as in prolonged lactation. Many cases of dysmenorrhea occur in girls with hypoplasia of the uterus, but with well-developed ovaries, the ovarian secretion stimulating muscular contraction of the uterus, at the same time congesting its mucosa. Chlorosis, Basedow's disease, the ill-effects of the menopause and castration, osteomalacia, eclampsia, and chorea are also in large measure directly or indirectly due to lack of this secretion. Clinical reports give ovarin as the best remedy for all these conditions; and though it is not probable that ovarin replaces all that the ovaries should furnish, or that it can easily overcome long-existing injuries, yet it must begin a new era in the treatment of diseases of the female.

Laboratory Milk.—A good milk, writes W. P. Northrup (*N. Y. Med. Jour.*, Mch. 16, 1901), is a mixed milk from herds of native breeds. Clean milk means that in which no bacterial toxins have been produced. A few bacteria do no harm, toxins poison. Laboratory milk is cooled below 40° F. within ten minutes of the milking, for at such temperature bacteria cannot grow. The cream is removed by centrifugation, the remaining milk being diluted and added to the cream according to the proportions required. Home-modification has often been a failure, owing to carelessness and ignorance of bacteriological cleanliness, and a mother's over anxiety to have the infant gain

weight. There are three formulæ necessary to remember: (1) For the newborn, fat 2 per. cent., sugar 5 per cent., proteids 0.75 per cent. (2) Low-average breast-milk, fat 3 per cent., sugar 6 per cent., proteids 1 per cent. (3) High-average breast-milk, fat 4 per cent. sugar 7 per cent., proteids 2 per cent. In from eight months to a year have the milk approximate cow's milk so as to wean the child. All feedings should be milk during the first year, mostly milk during the second year.

THERAPEUTIC HINTS.

Trinitrol.—Huchard uses tetranitrate of erythrol or trinitrol as a vasodilator of more lasting effect than amyl nitrite or nitroglycerin. The average dose is 0.01 cg. (gr. 1/6) every four hours.—*La Presse Méd.*, Mch. 6, 1901.

Lavage in Hematemesis.—Blood in the stomach stimulates the digestive act, causing increased peristalsis and the pouring out of gastric juice. This prevents the retraction of the bleeding vessel or clotting and favors a continuation of the hemorrhage. Linossier, therefore, considers lavage an indication in hematemesis. Bondet has obtained good results by treating simple ulcer of the stomach by lavage with a weak solution of ferric chloride.—*La Presse Méd.*, Mch. 6, 1901.

Mixed Feeding of Infants.—It is very common for mothers to give their nurslings a light pap, some milk, meat broths, toast, crackers, etc., without harm, and probably with benefit always after the fifth or sixth month. The indications for the use of artificial food as an auxiliary to human milk are: (1) Deficient quantity of mother's milk. (2) Deficiency in solids in human milk—a little cow's milk and meat juice may be a gratifying addition. (3) Excessive proteids causing colic and indigestion—some dextrinized gruel, condensed milk, or dextrin food, such as Nestlé's given just before nursing has a happy effect. (4) Diarrhea from human milk. Dextrinized gruel as above will answer. (5) Constipation—additional feeding acts well—two or three feedings a day of fat 4 per cent., proteids 1 per cent., sugar 7 per cent., or a few ounces of albumin water (white of one egg in 10 ounces of water) sweetened with cane sugar. Frequently oatmeal gruel relieves constipation, also the malted preparations, and pure butter. (6) The human milk is toxic. There are certain indications for the use of human milk as an aid to artificial feeding. Half to one ounce of human milk may be obtained by the breast-pump or cupping-glass, or by manipulation, and is added to the artificial food. It promotes the digestive and absorbing functions, tones the vascular system, and supplies antitoxic and bactericidal properties to the blood. The indications are: (1) Marasmus—Sometimes a little human milk for a week will start the baby on the right track. (2) Gastro-enteric infection—Clean out the alimentary tract, give large quantities of water, rice water, or barley water for 2 or 3 days; then add human milk to this, gradually increasing, until it can be replaced by cow's milk. (3) Rickets with tetany—Especially those cases with great irritability, laryngospasm, eclampsia, etc. With the use of an antispasmodic, preferably chloral, the addition of human milk to the artificial food greatly enhances the chance of cure. (4) Scurvy—Fruit juices, fresh cow's milk, white of egg, and human milk may be alternated.—*J. Zahorsky, Pediatrics*, Mch. 15, 1901.

Ergotine in Hemorrhage.—Ergot excites contractility in smooth muscle, especially in that of the uterus, but also notably in that of the vessels, especially the arteries. The researches of Vaquez show that the first manifestation is an increase of pressure in the venous system, and a lowering of pressure in the arterial system, followed, however, by a slight general increase in vascular tension. It does not affect the coagulability of the blood, therefore is not effective in the bleeding of hemophilia, anemia or jaundice. The hemostatic effect will be most marked in tissues rich in smooth muscle, most of all in uterine hemorrhage, somewhat in bronchial, not much in pulmonary hemorrhage, and very uncertain in epistaxis. In gastro-intestinal hemorrhage as in gastric ulcer, or typhoid fever, contraction is to be avoided for peristalsis may induce perforation, therefore ergot is not indicated, but in hemorrhoids it gives good results, although in general it is contra-indicated in venous hemorrhage. If a wounded artery is small so that clotting may take place during the stage of hypotension ergot is indicated, otherwise the secondary increase in tension will be harmful. Alfred Martinet prefers the hypodermic administration using:

℞ Ergotin "Bonjean" .....gm. 2.0 (ʒss)
Glycerini..... }
Aquæ dest. ..... } aa gm. 10.0 (ʒiiss)

Inject 1 to 10 ccm. (♏xv—ʒiiss) in twenty-four hours.

In the continuous hemoptysis of passive congestion from heart disease one can prescribe 5 to 12 of the following each day:

℞ Pulv. digital .....
Ergotin "Bonjean" .....aa gm. 0.05 (gr. 5/6) in pil No.1.

It may be used in liquid form:

℞ Ergotin .....gm. 1.0 (gr. xv)
Syr. aurant. cort } .aa ccm. 60.0 (ʒij)
Aq. dest. ..... }

For hemorrhoids employ a suppository of:

℞ Aq. ext. ergot gm. 0.20-0.80 (gr. iij-xij)
Ol. theobrom. .....gm. 4.0 (ʒj)
—*La Presse Méd.*, Mch. 6, 1901.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 6, 1901.

ADVERTISING IN THE PROFESSION.

We present in this issue an article by Dr. G. Frank Lydston, comprising a speech delivered at a recent symposium of the Physicians' Club of Chicago, which contains food for reflection. However ethical he may deem himself, the fact remains that the reputable physician must of necessity advertise in one way or another. It is so often difficult to draw the line that it is small wonder that some men lay themselves open to adverse criticism. The question is often one of good taste rather than ethics, and for some inscrutable reason the standard of what is and what is not permissible, varies with the locality. A man located in a country town may emblazon his specialty on his front windows and yet not lose professional caste. This is one of the glaring inconsistencies of our ethics, for the would-be high-toned city specialist cannot do the same and remain one of the elect.

Dr. Lydston is unsparing in his denunciation of the fee-commission business and justly considers it lower in the advertising scale than paid, column-rate "ads." in the daily papers. He very properly holds that the employment of advertising and drumming agents is of the same kidney as the fee-commission business. It would certainly seem that toleration of such methods by a profession which ostracises the advertising quack is absurd. In regard to newspaper notoriety, Dr. Lydston very aptly remarks that it is chiefly condemned by the man who does not get it. If we construe his meaning properly, he believes that there is a legitimate newspaper prominence open to medical men which helps the profession at large by making the doctor in general a more potent factor in the body social. He condemns, however, the exploiting of cases and the inviting of reporters to clinics. Dr. Lydston believes that the contribution of signed quasi-scientific articles to the public press will serve to down quackery by educating the people to a correct appreciation of the merits of scientific medicine. He holds that we must educate first, then try to legislate against quackery. There is much of truth in this view. It would certainly be better to let the public into our confidence first-hand, rather than to permit it to acquire misinformation from garbled and second-hand sources.

It is evident that Dr. Lydston believes that we are in the throes of an impossible attempt to make the ethics of a half a century ago fit accurately present conditions. This is the matter in a nutshell. While many may disagree most emphatically with some of his views, no one will question the frankness and fearlessness of Dr. Lydston's expressions, nor is any one likely to overlook the obvious fact that his views are based upon close observation of professional conditions as they are, not as we would fain believe they are. We believe also, that all will agree that, however unacceptable his views may be, he is actuated by a true spirit of professional altruism. He certainly is not trying to curry favor at court.

THE STATUS OF THE COUNTRY DOCTOR.

The position of the country doctor in England in the matter of position and influence, as set forth in a paper by Dr. Harry Roberts in the *Lancet* of March 16th, interests us as giving a very broad and hopeful view of the possibilities that lie within the grasp of our medical men to become a strong social power and influence in the small cities and towns in which they practise.

His experience is upheld by our own that to a large extent the village doctor has nowadays much of the influence formerly wielded by the parson, who used to be the only educated man in the parish.

With the greater culture that has come with the modern education of physicians there have come greater tolerance, greater sympathy and understanding, which are the basis of greater power and influence. By no means would he intimate that this culture should take the place of medical skill, but rather that it should supplant that old-time pomposity which has stimulated many an English wit to caricature.

This pomposity of the past he attributes to a lack of any general knowledge outside of medical and surgical information, as well as to a lack of humor. "Our venerable priggishness," he says, "our owl-like expression, our grave shakings of head, our solemn hat and coat, gave to the gods, and to any one who knows on what shallow pretence these absurdities were based, food for many hearty peals of laughter. Even now we are respectable or nothing. Strip us of our respectability and we cannot as a herd be told from a crowd of deacons—the same smugness and the same lack of humor, the same worship of the sacred Mrs. Grundy, the same fear of overstepping the stupid little laws and customs which prevail among the ignorant middle classes of our country districts."

Though class distinctions are not as sharp in American provincial life as in its English counterpart, it is none the less true that it lies within the physician's power to make country life less narrow and ignorant, more pleasant and cosmopolitan. On account of the intimate and peculiar relations with people of every class, broad-minded and sympathetic physicians may become the true directors of country social life.

On the whole we may conclude with Dr. Roberts that the position of country doctors is better to-day than it has ever been, and that if they play the game skilfully and fairly, and take to heart the satires of the humorists they may still further improve their status, their influence, and consequently their power of modifying the structure of provincial life. This is no despicable destiny.

DIFFERENTIATION BETWEEN HUMAN AND ANIMAL BLOOD.

One of the greatest questions in medical jurisprudence is that arising from our inability to determine the source of the blood stains found in criminal cases. There now comes to our aid the result of investigations made by A. Wassermann and A. Schütze in the Institute for Infectious Diseases in Berlin. (*Berliner klinische Wochenschrift*, February 18, 1901).

As a result of the authors' work, they have been able to demonstrate clearly the practicability of differentiating between blood of the human species and that of any other member of the animal kingdom. This also independent of the age of the blood stains. Their investigations are based on the work originally carried out by Bordet and later by Uhlenhuth. The former investigator proved that when an animal was injected subcutaneously with blood derived from some other species, certain products were produced in the blood of the former which had a specific influence on the red blood cells of the other animal when put in contact with them. These products were termed agglutinine and hemolysine for they caused respectively, coagulation and solution of the red corpuscles. Similar results were obtained when injections of milk from one animal were made into another. The authors, however, have pursued their studies further. They demonstrated that when cow's milk was injected subcutaneously into an animal, the resulting products in the blood of this animal would coagulate and precipitate the casein in fresh cow's milk, but not the casein in human milk or in goat's milk. Likewise, goat's milk would cause products which would not coagulate casein in cow's milk and human milk, but only that in fresh goat's milk.

From the result to the investigation of similar reactions with various animals' blood was a natural step. At first, human blood was used entire but as it was found that in order to obtain good reactions the blood needed to be comparatively fresh and the corpuscles intact, other means were imperative. These were the subcutaneous injections of human blood serum (entirely free from corpuscles)—each injection of about 10 c. c.—into the body of a rabbit. Five or six injections were made at intervals of two days. Six days after the last injection the blood was withdrawn from the animal and placed on ice for the separation of the serum. If a physiological sodium chloride solution of human blood or a diluted blood solution (with distilled water) be treated

by the addition of 0.5 c. c. of this prepared rabbit serum, at the temperature of the room, a rapidly-forming cloudy precipitate is produced which may be made more intense by subjecting it to a temperature of 99° F. in a warming oven. The question arises as to whether this precipitate is specific in character, *i. e.*, whether only human blood will thus react. The authors answered this by treating diluted blood solutions of all common animals; mammals, birds, fishes, altogether twenty-three species, with such prepared serum. In no case did the reaction just described occur. Only in a single instance can it be said to have been doubtful—and this instance in itself is highly interesting—namely, with the blood of a monkey. In this case the precipitate took much longer to form and was not as pronounced as with human blood. It shows the relation of man with ape in still another phrase—the albuminoid bodies in the one have a strong resemblance to those in the other.

All these experiments have thus far been with freshly prepared blood only. In order to demonstrate the practicability of the test with all blood notwithstanding its age, Wassermann and Schütze prepared specimens of all kinds of animal blood and allowed the blood stains to dry and lie about for three months. In this time, the characteristic changes to methemoglobin had occurred and the blood spots had become dirty brown in color. The spots were washed out with salt solution and treated as above being placed in a warming oven at 99° F. to insure better results. Also, the solutions were first carefully filtered in order that a perfectly clear and pure liquid should be used. In about twenty minutes the specimens were examined and the results bore out everything that had been hoped. The human blood solution was clearly in a state of cloudiness while all the others were unchanged. The blood solution of the ape had a faint trace of beginning precipitation. These reactions therefore will serve in any cases of blood examination, where the source of the blood is in doubt.

How important such a decided advance in medico-legal examination is, it is not necessary nor incumbent upon us to state. Suffice it to say that the results are brilliant and the field they open for further research practically limitless.

ECHOES AND NEWS.

NEW YORK.

New York Medico-Surgical Society.—At the annual meeting of the New York Medico-Surgical Society, held at the Hotel Manhattan, Saturday evening, March 16th, the following officers were elected: President, Robert A. Murray, M.D.; Vice-President, A. R. Robinson, M.D.; Member of the Executive Committee, W. Duff Bullard, M.D.; Secretary, J. Arthur Booth, M.D.; Treasurer, William M. Leszynsky, M.D.

Smallpox in New York.—The smallpox epidemic is by no means abated. There were some 44 cases reported last week and at least 40 the week before.

The Anti-Expectoration Crusade.—MagistrateMott is doing his duty nobly in the matter of the "spitting nuisance." He has dealt rigorously with all offenders and his attitude should be warmly commended by the medical profession. The device adopted in some communities of having the conductor present a small card containing the city ordinance to every offender is worthy of imitation.

Civil Service Examinations.—An examination for physician, first and second grades, will be held April 27th, by the State and County Civil Service Examiners. Salaries, $600 per year and maintenance. Eligible list will be made up on the basis of the standings obtained by candidates in the examination for license to practise in the State of New York.

Academy of Medicine.—On Monday evening, April 8th, the Section on Surgery meets. Dr. J. P. Tuttle will read a paper on Cancer of the Rectum with a demonstration of a new method of examination. On Wednesday, April 10th, the section on Otology will meet. Dr. H. L. Swain will show specimens of Tuberculosis of the Ear; Dr. Thos. J. Harris will read a paper on Tinnitus Aurium; some remarks on its causes and treatment, and Dr. Wm. P. Brandagee will read a paper on Tympanic Vertigo, Due to Obstruction in the Eustachian Tube. The following were recommended for election to Resident Fellowship: Drs. F. Bierhoff, James B. Clemens, Alexander Duane, W. Travis Gibb, W. C. Kubin and B. F. Tilton.

Reception to Academy Fellows.—At the Academy of Medicine Friday night, April 5th, Dr. A. Jacobi gave an informal reception to the Fellows of the Academy of Medicine and friends. The occasion was a semi-centennial anniversary of Dr. Jacobi's graduation as a physician and which gave him the opportunity to meet his friends and to thank them for the many courtesies of past years. The affair was informal and very pleasant. Dr. Jacobi read a paper, mainly historical, on the

development of medicine as shown in the teachings of the early part of the century:

With that perception of underlying causes that marks the man who knows nations as well as individuals, Dr. Jacobi summarized the tendencies of medicine in the first half of the century in Europe, the sober practical method of clinical experiment in England, the revolution of medical science under Bichat in France and the sad influence of the romantic and imaginative tendency of German metaphysics that gave rise to the narrow-minded theories of medicine. Having begun his medical studies in 1847 Dr. Jacobi, possessing that perception that sees the spirit of advance, had the good fortune to watch the intellectual revolution of Germany, and to see the rise of modern scientific medicine, based on the biologic discoveries established by Virchow.

The names of the men who were the leaders of medical thought in Dr. Jacobi's student days are many of them incorporated in the terminalogy of medicine, some were the propounders of totally forgotten theories. There was Nasse, in Bonn, who thoroughly believed in animal magnetism and Ennemoser who explained the relation of Adam to Eve by that alleged force, and how to magnetize the trees in the field and the child in its mother. There was Moritz Ernst Neuman who wrote a general pathology in six big volumes, but who, Dr. Jacobi adds, "did not expect us to know it all, for he was a kind, humane man." Weber the anatomist and Bischoff who intimated to the independent young thinker who was paying his respects to him in a borrowed swallow-tail, that he unless he knew his wholly preposterous and utterly unintelligible text-book by heart he stood small chance of his diploma.

There was Conradi who believed that a "cold drink was the root of all evil," Langenbeck of whom the story is told that in the days before anesthesia when lightning speed was the characteristic of a great operator, he amputated a limb while a British guest was adjusting his spectacles to watch the operation. There were Lotze and Wagner and Kilian, all men who wrote books noted in their day.

Dr. Jacobi commented highly on a remark that Dr. Osler made a year ago, praising him for not having written anything for seven years after his graduation; but for two of those years, while shut from all communication with the outer world, he never saw a square inch of paper or more than a small pencil which he kept concealed in his hair. With his freedom he found a new freedom in medicine and "rejoiced in the fact that medicine was no longer and would never again be, the victim of a single theory, or the work of an individual man, but the results of ever so many thousands laboring in all countries and languages with the same methods for a common aim."

PHILADELPHIA.

Gift to Hahnemann Hospital. Property adjoining Hahnemann Hospital and valued at $60,000 has been presented to that institution by Mr. and Mrs. George C. Thomas. A nurses' home will eventually be erected on the ground thus donated.

Dr. Wood Improving.—It is stated that Dr. Horatio C. Wood is gradually recovering from the attack of nervous prostration brought on by overwork which has for several months obliged him to relinquish his lectures and private practice.

Dr. Keen Honored by Jefferson.—On Thursday evening, April 4th, an oil painting of Professor W. W. Keen was presented to the Jefferson Medical College. The painting was the joint gift of the students, faculty, and alumni of the College, and the staff of the hospital. The address of presentation was made by Dr. J. Chalmers Da Costa and the painting was accepted for the College by Hon. William Potter, President of the Board of Trustees.

Arthritis Deformans Treated by Ice Applications.—Dr. M. G. Tull recently reported at the County Medical Society a case of arthritis deformans greatly improved by the application of ice to the spinal column. The patient was a female of twenty-one who had marked deformities of the wrists and could scarcely walk with the aid of crutches. A long ice-cap was applied to the spinal column for a period of two hours morning and afternoon, this time afterward being reduced to one hour. Guaiacol carbonate was the chief drug given internally. The patient is now greatly improved, the wrist deformities have disappeared and she can walk two miles. A similar use of ice resulted in marked improvement in a case of inflammatory rheumatism. A notable effect in the latter case was the causing of somnolence where before there was obstinate insomnia.

Fangotheraphy.—Dr. W. C. Hollopeter, Professor of Pedriatrics at the Medico-Chirurgical College, presented a paper on the above subject at a recent meeting of the County Medical Society. Fango is a grayish-brown mud or slime found as a sediment in certain lakes of Italy. It contains iron, magnesium, sulphur, lime, etc., and does not lose its properties by transportation. Its use is indicated in diseases of the muscles, rheumatism, gout, local neuralgias, paralysis, etc. Fango at a temperature of 98° to 120° F. is spread on the affected part to the depth of 3 cm. and the patient enveloped in warm blankets. In from one-half to one hour the fango is removed with tepid water. Several cases of rheumatism, synovitis, etc., were reported in which excellent results followed the use of this material.

Philadelphia Academy of Surgery.—The guest of honor at the meeting of April 1st was Dr. John A. Wyeth of New York who read a paper on Amputation at the Hip-Joint for Sarcoma; Its Tendency to Recurrence. Dr. Wyeth spoke of the extremely malignant character of sarcoma, pronouncing it the most malignant tumor. Statistics of operations with the per-

centages of recurrences were given. Of 267 hip-joint amputations collected 131 were for sarcoma. Not counting complications, the immediate mortailty was 6 per cent. Of the 117 who survived, satisfactory histories were obtained in 83. In these there were 51 recurrences. The effects of pyogenic infection and the induction of erysipelas were considered. From a study of his own and other cases, Dr. Wyeth concludes that streptococcic infection has an inhibitory effect on the recurrence of sarcoma, and that it should be induced. Infection should be caused at intervals of not more than six months for at least six years.

In Favor of Vaccination.—The Supreme Court, in the suit of Charles J. Field against Martha L. Robinson, principal of the Keystone Grammar School, to compel her to admit his daughter, who had been refused admittance because she was not vaccinated, sustained the decision of the lower court, April 1st, which decided that the teacher was right in excluding the girl. The court said: "We think the court below did not err in the ruling referred to in the assignments. In Duffield vs. Williamsport School districts we held that school directors, in the exercise of a sound discretion, may exclude from the public schools pupils who have not been vaccinated. Whether a resolution excluding from the school pupils who have not been vaccinated is a reasonable one is to be judged in the first instance by the school directors. In the present state of medical knowledge and of the opinion of those having charge of the public health the courts will not say that such a resolution is an abuse of official discretion. It has not been shown to our satisfaction that the act of June 18, 1895, is unconstitutional. For the reasons above stated we dismiss the assignments and sustain the conclusion of the court below." This decision should be contrasted with the decision of Judge Dunne of Chicago, as reported in last week's Medical News.

The Incisions in Operations for Mammary Carcinoma.—Dr. William L. Rodman, of Philadelphia, Pa., read a paper by invitation on this subject, in which he emphasized the fact that the lymph-vessels are far more numerous and complicated than former anatomists had led one to suppose. Instead of one set, as thought by Sappey and others, there are five, two superficial and three deep sets. The arrangement of these superficial and deep lymphatics explains many interesting facts in connection with cancer of the breast. It offers a ready explanation of the clinical fact that carcinomata affecting the inner half or sternal quadrant of the gland are more quickly fatal than those occupying the axillary quadrants on account of the infection of mediastinal glands. The essayist had rarely seen cancer of the inner half of the gland that was not quickly fatal, and therefore loked upon the location of the growth as an important prognostic sign. The age of the patient is also of great importance. Cancer in young patients runs a rapid course. In three cases he had seen under thirty years of age, two died within a year, the third being now under treatment with every prospect of early death. The entire gland is to be sacrificed in every case of malignant disease. He also insisted that the gland should be detached from above downward, instead of from below upward, the reverse of what is usually done. It is inconsistent to remove the gland from below upward, and clear the axilla from above downward. The incision must include all the skin covering the tumor, and should embrace that over the entire gland. More recurrences are due to leaving infected skin behind than to any other cause, due no doubt to the desire to secure primary union without skin-grafting. There is a prejudice against skin-grafting on account of the additional time required and the scars which follow it. He then reviewed the merits of some of the well-established operations. He thought the essential features of the best incision in breast operations should be, first, the wound should be sufficiently large to include all infected skin. Second, it should expose the pectoral muscles from origin to insertion. Third, should uncover axillary vessels and nerves. Fourth, it should have regard for the future usefulness of the arm. Fifth, it should, if possible, admit of primary union without the necessity for skin-grafting. Sixth, the operation should be completed within a reasonable time. While many of the above conditions are fulfilled by Halsted's, Kocher's, Senn's, Warren's and other methods, he was much impressed with the superiority of the Warren operation, and considered it a valuable step in advance, inasmuch as it enables the surgeon to secure primary union even after the removal of very large tumors without the aid af skin-grafting. The device is simple, very easily carried out, and, in the three cases in which it was tried, it was eminently satisfactory.

CHICAGO.

Additional Members of Hospital Staff.—The following appointments of physicians and surgeons to the Assistant Staff of the Cook County Hospital have been announced: Drs. F. Gregory Connell, M. L. Goodkind, Arthur M. Corwin, Carl H. Andersen, B. W. Sippy, Henry F. Lewis, William E. Quine, A. B. Spach, W. A. MacFarlane, Bernard Fantus, John Edwin Rhodes, A. F. Lemke, J. M. Weff, Arthur D. Houghton, George F. Thompson, William R. Livingstone, David J. Doherty, H. J. Brugge, P. J. H. Farrell, U. G. Wandell, and John S. Davis.

Appointment of Dr. Egan.—Dr. James A. Egan, Secretary of the State Board of Health, has been nominated and appointed a member of the State Board of Health to succeed Dr. Peter H. Wessell, of Moline.

Injury of Phrenic Nerve.—At a meeting of

the Chicago Medical Society, held March 27th, Dr. William E. Schroeder read a paper on this subject. The tumor of the neck was so situated as to make division of the left nerve necessary. The patient made an uninterrupted recovery and suffered no inconvenience from paralysis of left side of diaphragm. In referring to the various authorities it was pointed out that most of the surgeons agreed that injury to this nerve was either fatal or very dangerous, and a contrast was made with physicians who did not seem to consider paralysis, etc., of this nerve or the diaphragm necessarily fatal. In the literature were found twenty-four positive cases and one by Stromeyer of contusion of the phrenic and cervical plexus in which recovery occurred rapidly. The last one was a doubtful case. With the speaker's own case there were eight cases, his being the first case of intentional division. He pointed out that several cases of reported phrenic nerve injuries are not such injuries at all, but have either been assumed to be such or have been mistaken for injuries to the pneumogastric nerve. The following conclusions were drawn: (1) From the clinical and experimental data, it would seem that the importance of the diaphragm as a muscle of respiration has been exaggerated; (2) that as the symptoms commonly described as caused by an irritation of the phrenic were uniformly absent, not only in the operation, but in all of the experimental work as well, it is safe to infer that they may have been due to something other than a simple injury to the phrenic; (3) that while from an anatomical point of view the diaphragm undoubtedly is innervated by branches from the intercostal nerves, this nerve supply is secondary to the phrenic and is insufficient to carry on the action of the diaphragm after a division of the phrenic; (4) that a division of the phrenic nerve, producing partial collapse of the lower lobe of the lung on the affected side and an atrophy of one-half of the diaphragm, might predispose to infection of the lung or be followed by a diaphragmatic hernia; (5) that a division of one phrenic nerve in man, resulting in paralysis of one-half of the diaphragm only, is not necessarily fatal.

Purulent Inflammation of the Middle Ear.—Dr. Henry Gradle read a paper with this title, the object of which was to present to the general practitioner the teaching of modern otology regarding the treatment of purulent otitis, as according to the author's experience the method found to be the most efficient has not yet been generally adopted. It is possible for the family physician to prevent the serous discharge from becoming purulent, since this guarantees the most rapid and most favorable course possible. Paracentesis should be done as soon as the diagnosis is definite. Before puncturing, the meatus should be disinfected, preferably by carbolic-acid solutions. It is then packed with sterile gauze and a large pad of good, absorbing material is placed against the auricle. There should be both perfect asepsis and some guarantee against secondary infection by the liberal use of boric acid powder in the gauze. No other treatment leads to such uniform good results. The palliative use of so-called ear drops, which at the best are totally inert, can only be condemned absolutely. Regarding prevention, Gradle mentioned that the family physician should call attention to the existence of adenoids when present as a prolific source of ear disease. He likewise condemned the improper and reckless use of the nasal douche or of any of its substitutes. He thinks the danger to the ear is lessened in cases of suppurative rhinitis (in scarlet fever, measles, etc.) by a freely used indifferent spray to remove the secretion.

GENERAL.

Woman Junior Surgeon.—Miss Marion Ross, who is twenty-seven years old, has been appointed junior surgeon of the Macclesfield Infirmary. She took high honors at Glasgow University.

St. Louis Medical Society of Missouri.—Saturday, March 30, 1901, the following papers were read: Preliminary Report of a Case of Total Extirpation of the Stomach with Presentation of Specimen, by Dr. N. B. Carson; Physiological and Clinical Aspects of Dr. Carson's Case of Gastrectomy, by Dr. Jesse S. Myer.

Editor of Vratch Dead.—Dr. Wenzeslaus Manassein, Professor of Medicine at St. Petersburg and editor of the leading medical journal of Russia, has just died at the age of sixty years.

Oldest Practitioners in Austria.—According to the *British Medical Journal*, Dr. G. Ritter von Hochberger, who recently died at the age of ninety-eight years, was the oldest medical practitioner in Austria. At Carlsbad he had practised for over seventy years, having been there when Goethe was treating at that famous "cure."

Medical Society of the Missouri Valley.—The semi-annual meeting of this society was held in Omaha, March 21, 1901, under the presidency of Dr. V. L. Treynor, of Council Bluffs. After disposing of fifteen interesting papers the members repaired to the banquet. Dr. D. C. Bryant acted as toastmaster, and introduced the following speakers: Preventive Medicine and Politicians, Dr. V. L. Treynor; How We Do It in Missouri, Dr. Chas. Wood Fassett; The Physician Himself, Dr. W. O. Bridges; A Specialist's Opinion on Too Much Talking, Dr. Donald Macrae, Jr. The next (annual) meeting of the Society will be held in St. Joseph, September 19, 1901, after which the members will be tendered a complimentary outing to Eureka Springs, Arkansas.

Appendicitis Club for Maine.—Ohio is not long to have the honor of a specialty in appendicitis clubs. Maine, it is reported, is to organize one.

Plague Situation in San Francisco.—Great

pressure is being brought to bear in San Francisco to learn about the report of the Commission sent to this city by the United States Treasury Department to investigate the bubonic plague. It is said that the report, which has been forwarded to Washington, establishes the existence of plague in San Francisco, of the type prevalent in epidemics of the disease all over the world up to the climax of those epidemics. At a conference with Governor Gage, and later with Mayor Phelan of San Francisco, just before their departure for Washington, the commissioners said that they had themselves found ten cases of plague. They said the situation was serious, and that to stamp out the disease there should be a depopulation of Chinatown and the establishment of a detention camp, and that in the end it would probably be necessary to wipe out Chinatown entirely. This, it is said, forms the substance of the report made to Washington. Dr. J. H. White, Chief of the Quarantine Division of the Marine Hospital Service, says that there is no danger if proper precautions are taken, but the State authorities refuse to sanction measures suggested by the quarantine officers and the Plague Commission, which the city authorities desire to take. There have been thirty-two verified cases of plague since March 8, 1900, three of them whites, including a white nurse. Several of the cases have been of the pneumonic and most highly contagious type. There are at least five cases not in the verified list of undoubted plague, one of them a white. The latest verified case was on February 24th. There is one case, a negro, now under examination. The statement of the plague situation given out at Washington by the delegation which Governor Gage sent there does not accord with the facts as they are known to persons not tied up to the policy of suppressing the truth for the sake of commercial advantage. Governor Gage denies there has ever been a case of bubonic plague in San Francisco and asserts that the reports are instigated by a conspiracy to rob the State of prestige in order that Northern Pacific interests may secure Oriental and transport trade.

An explicit statement giving the exact conditions regarding bubonic plague in San Francisco has been prepared for the Official Public Health Bulletin. A table is given showing that there were ten deaths from bubonic plague in San Francisco between January 1st and March 15th. Of the cases, those reported in February, six cases and deaths between February 5th and 12th were reported by a special commission appointed by the Secretary of the Treasury to examine into the plague situation in San Francisco. This commission consisted of Prof. Simon Flexner, of the University of Pennsylvania, Chairman; Prof. F. G. Novy, of the University of Michigan, and Prof. L. S. Barker, of the University of Chicago, Recorder. Plague has been reported in San Francisco officially in the public health reports since March 6, 1900, thirty-two cases (all fatal) having been reported and published in previous numbers of the public health reports, and the facts were reported in the annual report to Congress of the Secretary of the Treasury, dated Dec. 4, 1900. On the return of this committee to San Francisco, Surgeon White wired, on March 22d, that they had agreed to raise funds for immediate work as follows: Disinfect all infected houses, provide hospitals for suspects, detention houses and morgue; the general disinfection of Chinatown, with betterment of light and air space. Subsequent telegrams show that the work is being organized. The disease has been confined almost exclusively to the Chinese and an examination of the mortuary records of the latter for the past four years shows that there has been no time during that period when it has increased to such an extent as to, in itself, cause alarm.

Obituary.—Dr. Edward B. Lighthill died suddenly at his home in Newark on Monday afternoon. He was born in Würtemberg, Germany, and was graduated from the medical department of Frederick William Hospital. He formerly practised in Newark and while a resident of that city married Miss Illinois Sherman, a relative of Gen. William T. Sherman.

Medical Director William T. Hord of the Navy died in Washington April 1st. He held the relative rank of Captain on the retired list His naval service covered a period of nearly forty years. He was born in Kentucky and was about seventy years old. He was a volunteer aide on the staff of General Nelson from the battle of Pittsburg Landing to the evacuation of Corinth, Miss., by General Beauregard. On the steam sloop "Pawnee" he participated in all the operations against Charleston under Admirals Dupont and Dahlgren and General Gilmore. He was commissioned Medical Director May 1, 1879, and was retired on account of age in 1893.

Dr. William Fleet Luckett, a prominent physician of Washington, died at his home in that city yesterday at the age of sixty-three years. He was born in Loudoun county, Virginia, was graduated from the University of Louisville in 1860, and served throughout the Civil War as a surgeon in the Confederate Army.

Dr. James H. Rogers of East Hampton, Long Island, died March 12th at the Grand Union Hotel, New York. He had just recovered from a Bottini operation when he was stricken with lobar pneumonia and died on the fourth day. He was born in New York, September 1, 1829; graduated from Williams College in 1852, and from Jefferson Medical College in Philadelphia four years later. He then went abroad where he pursued his medical studies for two years in Paris. He then located in New York until the outbreak of the Civil War when he became a Surgeon to the 7th Regiment of New York Volunteers, and had medical and surgical charge of Fort McHenry for a time. In 1865 he located in Sag Harbor, Long Island, and the next year was mar-

ried to Miss Georgia E. Starr of that place, who survives him. In 1894 he retired from active practice and located in East Hampton. His father, Nathan Rogers of New York, was one of the foremost miniature portrait painters of his day, and was one of the founders of the Academy of Design. Dr. Rogers was small of stature and frail of constitution; however, his intellectual attainments were of a high order, and he was positive and resolute in his conclusions. He continued active in the recent advances in medicine to the very last. He had been a most painstaking observer, which, with his wide attainments, made him a most valued consultant. Of him, it can be truthfully said, "He was a gentleman of the Old School."

American Academy of Medicine.—The twenty-sixth annual meeting of this society will be held at the Hotel Aberdeen, St. Paul, Minn., on Saturday, June 1, 1901, at 11 A.M. (Executive session); the open session beginning at 12 M. and continuing through Monday, June 3d. The principal features of the meeting will be a symposium on "Institutionalism"; and another on "Reciprocity in Medical Licensure." Series of valuable papers on both topics have been promised, as well as interesting papers on some other subjects. The President's address (Dr. S. D. Risley, of Philadelphia) will be delivered on Saturday evening, June 1st, and the Annual Social Session held on Monday evening, June 3d.

CORRESPONDENCE.

AN ANTAPHRODISIAC OF SOME MERIT.

To the Editor of the Medical News:

Dear Sir: During the past year I have used the following prescription in my practice in a number of cases. It was prepared to stimulate the hepatic secretion, to improve the condition of the kidneys, and to strengthen the nervous system. Somewhat to my surprise, I noticed in some of my first cases a marked abatement of previously strong sexual proclivities. I continued using it in my practice, and found it to restrain the venereal appetite in both sexes to a marked degree. Judging from reports of the difficulty of solving the social evil problem, there is much need of reliable and energetic antaphrodisiacs. No bad effects following the use of the remedy in my cases have been noted. There is simply a subsidence of desire, while all the physical functions are performed as usual. Believing that there is an excellent opportunity for testing the virtues of the combination on a large scale, it has appeared to me proper to offer it as a small contribution in aid of a worthy cause. Hoping that it may be a seed planted in good soil, and that it may produce a hundred fold, it is here given:

℞ Tinct. cubebs.....5ss
Kola cordial, P. D. & Co.....5i
Fl. Ext. wahoo.....5iii
Syr. simpl. ad.....5iv
Misc. Sig. One teaspoonful in water fifteen minutes before meals and at bedtime.

John I. Ligget, M.D.

Ladiesburg, Md., March 7, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, March 25, 1901.

Death of Queen Victoria's dentist—Court medical appointments—The late Queen's favorite physician—Decorations for doctors—Professional earnings—Reciprocity of medical practice between Great Britain and Italy—The International Congress on Tuberculosis.

Queen Victoria has been quickly followed to the grave by her dentist Sir Edwin Saunders. He was the first English Knight who ever won his spurs by his prowess with the dental forceps. If he had not the ear of the Queen, he at any rate had her jaw, for he had official charge of the royal teeth for more than half a century. But as he was several years older than his august patient, his post was for a considerable time before her death almost purely honorary. Another dentist whom the Queen consulted in her later years found her a distinctly refractory patient. Her Majesty at first peremptorily declined to follow his advice, and six months afterward sent for him, indicated it to be her will and pleasure to have the line of treatment carried out to which she had previously refused to submit, and found fault with him for not having recommended it.

It is considered in our snobocratic old Europe a high honor to have medical charge of the person of the sovereign, but it is an honor which it needs a certain suppleness of spine to carry with comfort. If it be true that "uneasy lies the head that wears a crown," it may also be said that uneasy stands (for etiquette forbids his sitting) the physician who has the care of that head. He knows that his reputation is at stake, for if things go wrong he will be held accountable, and he will ever after be like Othello, "a fixed figure for the time of scorn to point his slow unmoving finger at." The death of Napoleon the Little has always been attributed by the public to the blundering of his doctors, and in his recent book on Napoleon the Great, Lord Rosebery speaks contemptuously of the banished Emperor's medical attendants, for no better reason apparently than because they failed to cope successfully with cancer of the stomach.

On the other hand, if a physician or surgeon gets the credit of having cured any ailment from a cancer to a cold in the person of roy-

alty, he tastes how sweet are the uses of advertisement. What is called "Society" here is very like what it was in France in the days of Louis XIV., when Felix, the surgeon who operated on the royal fistula, was overwhelmed by courtiers clamoring for a touch of the knife which had been plunged into the rectum of the Lord's anointed. A doctor who is known to attend royalty wears around his head, in the eyes of the loyal Britons, a halo of light reflected from the central luminary of our social system. *S'il n'est pas la rose, il a vécu près d'elle.* A story used to be told of a Court doctor, who has long since gone to that unprospected country where kings and costers mingle their dust, which illustrates at once the innate flunkeyism of so-called "smart" people in England, and the profitable uses to which this amiable weakness may be put by a shrewd practitioner. He had on the mantelpiece of his consulting room a bottle full of a liquid which he exhibited from time to time to privileged persons as the renal secretion of a beautiful Princess, who has now reached a more exalted position. The faithful paid cult to this interesting relic with as touching a devotion as any pilgrim in the ages of faith ever brought to the holiest shrine; their offerings enriched the priest of science who guarded the sacred spring, and his fame was in the mouths of all who formed part, or wished to be considered as forming part of, the world of fashion.

Of course, all Court physicians are not men of this stamp. Sir William Jenner never stooped to servility and spoke his mind with a bluntness which did not always please ears attuned to tones of deference and flattery. When Lord Beaconsfield, who was a special favorite of the late Queen, was stricken with the illness which proved fatal, Her Majesty asked Jenner to visit the dying statesman. "Dizzy," who like many politicians, at any rate in Europe, had a poor opinion of doctors in general, had given his health into the keeping of a physician who had practised homeopathy and still, rightly or wrongly, lay under suspicion of that heresy. Jenner refused to meet him. The Queen insisted, and Jenner at last said "I am your Majesty's servant and I am bound to obey your command. But I must ask to be forthwith relieved from a position in which I am liable to have such a command laid upon me." The Queen was not accustomed to have her will opposed, but in the face of this firm attitude of her trusted physician, she thought it well to give way. Jenner then offered to visit Lord Beaconsfield on condition that he was not to be expected to acknowledge the unorthodox practitioner. It is related that in order to make it plain that he would have no dealing with heresy, he carefully kept his back turned towards his "separated brother" all the time he was in Lord Beaconsfield's room. Jenner's salary as Physician to the Queen was understood to be $20,000. Of course the appointment was worth much more to him as an advertisement. But the duties were very onerous, and a good many years before his final abandonment of practice he would have been glad to give up his attendance at Court; he did not care to do this, however, partly out of personal regard for the Queen, but mainly because it would have involved his retirement from active professional life, a step which he could not afford to take.

The position of physician in ordinary to the sovereign has generally been held by a man who has gained a leading place in the profession in the arduous path of hospital work and teaching. It is in fact regarded as one of the chief prizes for a profession in which prizes are few. Sir James Clark, however, Queen Victoria's first physician, in whose hands she was for the first twenty years of her reign, was originally a surgeon in the navy and was never a hospital physician. Nevertheless the royal family had unbounded confidence in him, and he fully justified the trust, though in the early days of his connection with the Court he fell into an error of judgment which had very painful consequences. Sir. James Reid, again, who succeeded Jenner has never been a consulting physician in the ordinary sense. For some years he was resident physician with the Court, a position in which he succeeded a Dr. Marshall who held it for twelve years. During all that time Marshall hardly ever saw the Queen, except at a distance and he had but one brief holiday. Short as it was it was interrupted by a summons to Baveno where John Brown, the Queen's personal attendant, had been taken ill with some trivial ailment. Although an eminent physician, the late Dr. Wilson Fox, was in attendance, Brown insisted on having Dr. Marshall sent for, and the wish of so important a personage had to be obeyed. When Marshall resigned his post, there were naturally a great many candidates for the vacancy. To these aspiring youths Jenner, with characteristic plainness of language, explained the precise position which the resident physician had to occupy and the duties which he had to perform. This had the effect of checking their vaulting ambition, and for a time it was difficult to find any one to accept the post. One man was induced to act as a stop-gap and gave such satisfaction that he was urged to stay on. After three months, however, he could stand it no longer, and he has since been heard to say that he would not have taken the permanent post for $50,000 a year. The duties were light enough, being little more than prescribing an occasional nerve sedative for a Maid of Honor or an aperient draught for a "dresser," as the Queen's tiring women are called. The resident physician was never allowed to try his prentice hand on the sacred person of "Her Most Gracious." The life was lonely and

dull; the unhappy man was cribbed, cabined and confined in the iron cage of etiquette. He could not leave the house till the Queen went out for her daily airing; he could not smoke except at certain times and in certain places, as the royal nose was offended by the fumes of tobacco; he had no one to speak to, except the lower officers of the Royal Household who looked down upon him as a being of commoner clay; he had no convenience for study and little opportunity of practice, with the result that he was in danger of forgetting whatever professional knowledge he had acquired. A position more intolerable to a man of any spirit could hardly be imagined. And against these manifold disadvantages there was not even the consideration of a good salary to be placed. Court appointments are in general poorly paid, as the honor of serving royalty is regarded as in itself a reward for the most self-sacrificing devotion.

Sir James Reid's Court career has been very different from that of his predecessor. He has, indeed, been the spoilt child of fortune. He won the Queen's confidence not only as a physician but as a counsellor in her very extensive and complicated family affairs. With an industry which can only be described as heroic he mastered the family tree of the Guelphs with its innumerable ramifications through an infinite series of relationship and affinity to the *nth* German cousin. Her Majesty valued his advice because he always said just what he thought. But the burden was sometimes almost more than he could bear. One day at Cimiez he begged one of the local physicians to invite him to go out for a drive, as he had had to listen for four hours to some more than ordinarily tangled web of family trouble, and, in accordance with etiquette, had been standing all the time. It is no secret that ladies in waiting sometimes fainted after standing for hours in the presence of royalty, and even strong men broke down in health under the exacting duties of attendance on the person of the Sovereign.

Though Sir James Reid has contributed practically nothing to medical literature, and owing to circumstances has had relatively little experience, such is the divinity that doth hedge a throne that if he chose to put his name on a brass plate in a fashionable quarter, his door would be besieged by patients. It is said, however, that he intends to be content with a quieter, if less lucrative, mode of life; and this decision is probably a wise one.

The King has conferred on Sir Thomas Barlow and Sir Richard Douglas Powell, who, with Sir James Reid, were in attendance on the Queen in her last illness, the Kinghthood of the New Victorian Order. Edward VII. has not yet chosen his own Medical Establishment, but it is perhaps significant that he has within the last few days bestowed the same Order on Sir William Broadbent, his Physician in Ordinary when he was Prince of Wales. Sir William Broadbent has probably the most remunerative practice of any pure physician in England.

It may be mentioned that $50,000 is about the high water mark of professional income for pure physicians here. Some operating surgeons, especially those who have taken the abdomen for their province, earn a good deal more. Their fees are high and they often add to their strictly professional gains an unearned increment derived from "nursing homes" to which they send their patients. The charges at some of these homes are very high and the surgeon who plays the part of tutelary genius is believed to take the lion's share of the profits.

From an official announcement made in the *London Gazette* of March 19th it appears that the Privy Council has administered a snub to the General Medical Council, which is the body having most direct power over the medical profession in this country. As you are aware, the cry of "Italy for the Italians" was raised some time ago by the medical profession in the dominions of King Victor Emmanuel II. This fluttered the dovecotes of the British practitioners who minister to the medical needs of their countrymen in Italy. There has been a good deal of negotiation and wire pulling, and the matter would doubtless have been amicably settled by diplomatic action. But our Medical Council took a *Non possumus* attitude in regard to the recognition of foreign diplomas, and the Italians were equally determined not to recognize the diplomas of any country which refused to recognize theirs. It seemed therefore as if what has hitherto been an "open door" would be slammed in the face of the British physician in search of an Italian market. The difficulty has now been got over by the Order in Council by which full reciprocity of recognition of medical diplomas is granted to Italy.

The organization of the International Congress on Tuberculosis which is to be held in London this summer is proving to be a task of unexpected difficulty. It had been arranged that the Prince of Wales should open it in state. As a French monarch said, however, that the King of France did not remember the wrongs of the Dauphin, our new King does not acknowledge this particular engagement of the Prince of Wales. He sent a curt intimation to that effect to the organizers of the Congress when they humbly ventured to remind him of his promise, and they are now trying to secure one of the *minora sidera* of royalty to grace their meeting.

Physician Stabbed by Hospital Patient.—Dr. Johnson, a physician in the State Hospital for the Insane at Danville, Montour County, was stabbed to death to-night by an insane Italian patient.

SPINAL TUMORS—PYRAMIDAL TRACT FUNCTIONS—RARE RENAL TUMOR—VEGETARIANISM—TUBERCULOUS ANURIA — TWENTIETH ANNIVERSARY OF THE FOUNDING OF THE VEREIN FUER INNERE MEDICIN IN BERLIN—HYPERTROPHY OF THE PROSTATE—BONE SUTURE.

F. Krause, at the Berliner med. Gesellschaft, February 13, 1901, in presenting a case of tumor of the spinal cord cured by operation and in discussing this subject, observed that since the suggestion and introduction of the operative removal of these growths by Horseley thirty-seven instances have been reported of which thirteen were fatal. The later series of cases have been more successful than the earlier, for two reasons; first, very great improvement in the operative technic and, second, earlier and more accurate diagnosis of the neoplasms by the attending physicians. The thirteen fatalities above are such as are undoubtedly attributable to the operation itself. His seventy-six-year-old patient had been weak in the right lower extremity for five years following a traumatism, namely falling down a flight of stone stairs and repeatedly striking her back on the edges of the steps. Just after the accident she was not bedridden but experienced much lumbar pain. The speaker could find no evidences of gross lesion. Eight or ten weeks after the fall she began to have pains, paresthesias and paresis in both lower extremities, at first about the right thigh, later about the left. In May, 1897, girdle-sensation appeared and her state as a whole become worse. By May, 1900, her right lower extremity had become entirely lame. At this time on examination were found on the right side paralysis, girdle-sense and disturbed sensation, normal well-nourished muscles, normal tendon reflexes, normal electrical reaction. On the left side the extremity was entirely anesthetic and decrease in the temperature sense. Muscular sense was bilaterally normal. The picture was therefore that of a Brown-Séquard unilateral paralysis with a few alterations. The diagnosis made was that of tumor of the spinal cord. Its site was assumed to be intradural, because there was no tenderness to pressure or percussion along the vertebral column, and from the symptoms, at the ninth dorsal segment, between the seventh and eight dorsal spines. These were exposed freely through the soft parts and the arches of the seventh and eighth dorsal vertebræ were removed. Beneath them lay the dura very much distended. This was incised and a walnut-sized discrete tumor easily shelled out, leaving a slight depression in the cord. The operation lasted a few minutes. Recovery was prompt. Restitution, though not complete, was certainly far better than the dismal remote effects of the tumor if left *in situ*. Psammoma of benign character was the type of the growth.

M. Rothmann in a paper on the functions of the pyramidal tracts said that it had been thought that these had been separated from the others, but in later observations it was proved that this idea is erroneous. Of course, all observations and experiments have to be made upon animals and naturally in the development of the spinal cord in man and in the lower orders is different. The recent experiments of Starlinger, Schiff, the writer and others, have shown that in dogs and apes when these tracts are cut through the resulting paralysis is temporary, the muscles recovering their power in part or whole. The explanation appears to be that the centrifugal impulses pass down the tract of Monakow which crosses as a rule just above the pyramids and in the cord passes down just beside their path. Hence after a while these paths take up the function of those destroyed and more or less use returns to the extremities. Such is also the probable explanation of some of the recoveries after hemorrhage into internal capsule in man.

Schoenstadt, at the meeting on February 20th, showed an adenocarcinoma, removed from a child a few months old, who had developed it within one kidney. Such was pronounced very rare.

Alber discussed the possibility of a rigidly pure vegetarian diet and the relation it bore to perfect health. The vegetarians have long claimed that such is not only possible, but often the case among them. Only two well-proved, reliable cases of a faithful vegetarian diet are reported, however, one by Voit and another by Rumpf, jun. The writer begged to note a third. His patient was an exceedingly graceful, healthy female thirty-six years old, who for several years had eaten only vegetables. She allowed herself a five-day varied menu from which she made choice. This total comprised 120 grams of graham bread, 400 grams of apples, 200 grams of grapes, 460 grams of hazelnuts, 70 grams of dates, 100 grams salads, together about 1400 grams or 3713 grams per kilogram of body-weight. The percentage of nitrogen was 5.4+grams = 34.1 grams of egg albumin, fat in the nuts was 36 grams, carbohydrates, 225 grams. The quantity of urine was very small indeed; fecal matter abundant. With this very small quantity of food and extraordinarily limited amount of nitrogen, the patient still remained in good health and apparently suffered nothing from the scanty nitrogenous supply. If we admit the possibility of such a purely vegetarian diet as generally safe, it does on the whole and general rule appear to be not conformable to good judgment. There are however certain contra-indications and direct indications for it in therapeusis. It will be very serviceable in urticaria, pruritus, furunculosis, erythema ex-

udativa, multiformis and nervous, some disturbances of gastric indigestion, fatty tendencies, and neurasthenia. It will be inadvisable in many organic gastro-enteric diseases, as is self-evident to any observer.

The Verein für innere Medicin in Berlin celebrated the twentieth anniversary of its foundation on February 20th by a special meeting and on the 21st by a banquet. At the meeting Von Leyden was the recipient of the highest honors in the gift of the society in the office of Honorary President, presented by Gerhardt in a speech reviewing his services during the difficulties of founding the organization. Rothmann read a short list of newly elected honorary members. Von Leyden gave a history of the society since the first meeting and Litten, the Secretary, read an epitome of some of its most important transactions.

Pels-Leusden, at the Gesellschaft der Charité-Aerzte in Berlin, February 7, 1901, gave the history of a case of anuria in a female with a palpable tuberculous tumefaction of the right kidney. After three days of an active pneumonia, and notwithstanding it, the kidney was exposed and a large quantity of urine evacuated from the parenchyma and pelvis of the organ. Through a drainage-tube for several days urine continued to ooze. Finally, the bladder again began to discharge urine and the fistula soon healed. The explanation of this phenomena appears to be that the pelvis of the still secreting left kidney became blocked in some manner, perhaps by a clot, for example.

Braun, in a critical review of the various methods of treating prostatic hypertrophies, dwelt at length on procedures employed at König's clinic. This is simply the use of a large common metal catheter as a preventive of urinary retention. As a rule this is found to work well and produce a practical cure of long duration.

Martens stated that in the same clinic all recent fractures of the patella are now sutured, so also those of the olecranon process when apposition of the fragments by other means promises to fail. In fractures of the jaw, the patient is first turned over to the dentist and when he fails, the bone suture is tried. Other fractures complicated and uncomplicated usually do well under the old-style methods.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held Saturday, February 23, 1901.

The President, Howard Lilienthal, M.D., in the Chair.

Acute Contagious Conjunctivitis.—The paper of the evening was read by Dr. Edwin S. Steese on the common acute contagious conjunctivitis known familiarly as "pinkeye." This disease has taken on special interest of recent years because of its frequent occurrence in epidemic form in our large cities. In 1885 Dr. Weeks of New York began an investigation as to the etiology of the disease. The result of his studies was not announced until 1895. Every year, especially in the spring and fall, there were scattered epidemics of this form of conjunctivitis, which came to be known popularly as pinkeye. First one, then other members of a family were attacked by the disease, and its spread in schools showed that it was contagious. The English troops returning from Egypt brought the disease with them. Koch in his series of investigations in Egypt discovered that Egyptian conjunctivitis was due at times to the gonococcus and at other times to a slender bacillus, morphologically not unlike the micro-organism which causes mouse septicemia. English ophthalmologists at first were rather alarmed as to the importation of the disease into England, but it proved to be comparatively harmless and had none of the characteristics of the chronic conjunctivitis which exists in Egypt so commonly and which is so often obstinate to treatment.

Etiology.—Dr. Weeks of New York without knowing anything of Koch's researches found a bacillus resembling that described by the German observer. After obtaining this bacillus in a pure culture, Weeks inoculated it into the eyes of rabbits but without results. It was then tried on human beings and an acute conjunctivitis always resulted. The bacillus as described by Dr. Weeks is thinner and longer than the tubercle bacillus. When obtained from human secretions the characteristic bacilli are always distinctly separated from one another and their limits are well defined. When grown on culture media, the bacillus always grows in strings and the individual bacilli are not well defined.

Contagiousness of the Disease.—The disease is contagious so long as bacilli are present in the secretion and this is always for some time after the disappearance of the acute symptoms. There remains a stage of convalescence during which the disease is communicable to others. This accounts for the spread of the disease in epidemic form. As a rule the bacilli are found free in the secretions, but at times they occur in the cells of the secretions, in this resembling the gonococcus. Morax in France placed a drop of pure culture in the cul-de-sac of his conjunctiva at a time when absolutely no lesion of the conjunctival membrane was present. Conjunctivitis resulted.

Symptoms.—The first symptom is a congestion of the eyeball. Both sets of ocular blood-vessels, the internal and the external, are congested. At the beginning of the disease, many leucocytes are present in the tissues. At times congestion produces such a redness of the conjunctiva that the disease is sometimes spoken of as acute hemorrhagic conjunctivitis. Lacrima-

tion usually continues for three or four days, then muco-pus occurs on the conjunctiva and there is some gluing of the lids in the early morning hours, then the characteristic pink color, to which the disease owes its name of pinkeye, develops. At times the secretion is distinctly purulent. This may give rise to mistakes of diagnosis and a suspicion of the presence of gonorrheic ophthalmia may develop. There is slight chemosis, that is, edema between the conjunctiva and sclera; at times some constitutional symptoms, slight fever and headache being observed. Yellow masses are often found at the inner canthus of the eye and are characteristic of the disease. As a rule, the disease takes three weeks before it is entirely well and it may remain contagious even after this period.

Complications.—Certain cases of acute contagious conjunctivitis are complicated by phlyctenula or trachoma. Other complications are always due to secondary infections. The phlyctenula or trachoma may have existed before the conjunctivitis developed and then be somewhat exaggerated by the acute process. Corneal ulcer occurs very rarely in the disease. In 2,000 cases of the disease Weeks has seen corneal ulcer only once. Morax in France has seen six corneal ulcers. Still it is necessary to be on one's guard against the development of ulcer, though it is a rare complication. In a certain number of the cases where corneal ulcers were reported as occurring during the course of pinkeye, the corneal complication was undoubtedly due to the fact that it was not the Koch-Weeks bacillus, but some other micro-organism that was the causative agent in the production of the acute inflammation. The physician must be constantly on his guard not to mistake other and more serious conjunctival inflammations for pinkeye at a time when he knows that pinkeye is prevalent.

Treatment.—As soon as pinkeye is suspected, the patient should be isolated. To relieve the discomfort that occurs cold applications are the most soothing. In delicate children, particularly when cold applications are continued for a long time, care must be taken that the circulation to the cornea does not become so sluggish as to interfere with the nutrition of this important structure. At the slightest appearance of a hazy cornea cold applications should cease. The use of simple cold compresses is better than any antiseptic. The method of applying cold is to place small squares of linen on ice until they become ice cold and then apply them over the eyelids. The pieces of linen may be changed by the patient himself, whenever they become warm, that is every five minutes or so. During the acute stage of the disease, the eyes should be washed every half-hour with a two- to three-percent. solution of boric acid or a very dilute solution of bichloride of mercury. It seems almost impossible to keep the other eye from being affected when one has become diseased. The ordinary eye-shields are apt to do more harm than good, and their use in acute conjunctivitis is not approved by any of the authorities.

Protection and Immunity.—The disease affords no protection against itself and provides no immunity. Within a few weeks after an attack there may be a recurrence. The patient does not, however, seem to reinfect himself. After the acute stage is passed a solution of silver nitrate, one to one and a half per cent., may be used. This often seems to hasten convalescence. Where puffiness of the lids occurs and the case seems prone to run a chronic course, the silver-nitrate treatment is especially useful. The infectious agent apparently does not invade the lacrimal glands. Where the lacrimal glands are invaded, or where the ducts become infected, some secondary microbic agent is at work. This is usually the pneumococcus, but may be the streptococcus. When the latter agent obtains a firm hold serious purulent complications may ensue. Pinkeye in human beings is seldom accompanied by coryza, though ths is a very common symptom of a similar disease in horses. In ordering cold applications for the eye it is important to direct exactly how they should be made. The use of the little squares of linen that have been described, put on ice for five minutes or more and then applied to the eye, is the best method. Where specific directions are not given attendants may apply cold by means of a piece of ice wrapped in a handkerchief or a linen towel. The addition of pressure to the cold is nearly always a source of danger. The circulation is interfered with, the nutrition of ocular tissues is lowered, haziness of the cornea results and before long there is danger of perforation.

Ether Conjunctivitis.—Dr. John B. Walker said in the discussion that in a recent case in one of the hospitals, rather painful conjunctivitis developed as the result of the instillation of some ether into the eye, through carelessness on the part of the anesthetist. Cold applications were made to allay the pain. At the end of thirty-six hours, however, the patient instead of being more comfortable was suffering rather severely. The pain seemed actually to be increased. An ophthalmologist was called in consultation and he recommended the application of heat. He said that it was not an unusual thing to find that in certain patients cold rather increased the discomfort, while heat relieved it. In twelve hours the patient was at ease.

Differential Diagnosis.—Dr. Howard Lilienthal said that during an epidemic of acute contagious conjunctivitis every disease of the eye should not at once be diagnosed as pinkeye. There is danger that a gonorrheal conjunctivitis may be allowed to run its course without proper treatment for several days as the result of such a false diagnosis. The consequences of such an error would almost surely be serious for the patient. Microscopic diagnosis should be made in

every case, especially if any unusually severe symptoms are manifest. Dr. Lilienthal has seen haziness of the cornea develop as the result of the application of cold. He has had favorable experience with the method of applying folds of lint, but considered it a mistake ever to use more than four folds for an application, for when more are used they are apt to adhere to the lids.

Heat or Cold Applications.—In a recent case where a corneal abrasion resulted from a careless anesthetist's fingernail rather severe conjunctivitis developed. In this, as in Dr. Walker's case, while cold did no good, heat relieved the pain very soon. The cold that is applied is, of course, not enough to kill bacteria, but it may be sufficient to retard their growth and make the inflammation less severe. In a personal experience with pinkeye Dr. Lilienthal made applications of cocaine to the conjunctiva. These applications were continued until the conjunctiva was almost whitened. Not only was the discomfort lessened, but the disease seemed to run a shorter course.

Prophylaxis.—Dr. Henry Coggeshall said that in the first epidemic of the disease which he saw, it spread not only among the patients in the hospital, but also among the doctors, the nurses and the attendants. Only those members of the hospital staff escaped who were trained to keep their fingers out of their eyes. The disease runs in epidemic form usually during dusty seasons of the year. When the disease is known to be epidemic children particularly should be taught to wash their hands very thoroughly and frequently during the day and to rub their eyes as little as possible.

In closing the discussion Dr. Steese said that it is extremely difficult to protect the other eye from infection, though patients should be cautioned to guard it as far as possible. The use of a cover-glass as a rule is not advised. In a case of conjunctivitis where both surfaces of the conjunctiva are inflamed, heat is a better remedy than cold. There are two reasons for the use of cold applications to the eye. The one is the comfort of the patient and for this the choice of heat or cold depends somewhat upon the idiosyncrasy of the patient. The other reason is to limit the growth of bacteria by making the temperature of the ocular tissues unfavorable for them. It is much easier to lower the temperature of the tissues to a point where bacterial growth is retarded than to raise it sufficiently to produce a similar effect. Hence the more frequent use of cold.

Influenza and Typhoid.—Dr. Charles Schramm reported a case and exhibited a set of charts which showed influenza and typhoid running their course side by side in the same patient. The patient was first taken down with characteristic influenza symptoms of the catarrhal type. In a week the symptoms were better, but the pericardial complications developed and the second heart-sound reduplicated. The temperature continued high and the patient became alternately restless and apathetic. The temperature rose to 107° F. and some consolidation was discovered in the upper part of the lower lobe of the right lung. Recurrent chills developed with a temperature of 105° and 106° F. This was evidently the bronchopneumonic phase of influenza sequelæ. Spots of consolidation formed here and there in the lungs, but disappeared in thirty-six hours. During the course of the typhoid fever an alarming hemorrhage came on. The nurse became confused and a heavy ice-bag was applied directly to the skin and allowed to remain for some time. As the result of this an eschar developed in the right inguinal region with loss of the cutaneous tissues. The resultant sore took a long time to heal. After three weeks of characteristic typhoid, lysis of the fever took place and everything was going on well, when a relapse occurred. This secondary typhoid was complicated by hemorrhage and by a septic condition. Notwithstanding this alarming series of accidents the patient is recovering.

Unusual Typhoid Accompaniments.—Dr. Howard Lilienthal said that he had recently operated on a case in which a medical man said that typhoid was beginning. There was a history that pointed to the existence of cholecystitis. He operated and removed an amount of pus from the gall-bladder and a number of stones. The patient recovered without incident, but the typhoid fever ran its course without any interruption. Dr. Lilienthal has seen superficial sloughing occur from the injudicious use of ice-bags. The possibility of this does not seem to occur to most people. Special care is to be taken in this matter in stout patients. The nutrition of the fat tissue of the abdomen is low in resistive vitality and an almost gangrenous condition develops on very slight provocation.

Dr. Walker said that he has seen some cases in which ice-bags used too freely on stout patients have produced sloughing. In one case of a very stout person a slough eight inches in diameter occurred, which proved extremely obstinate to treatment. If used without discretion ice-bags may cause a cutaneous condition much worse than the internal condition for which they are employed.

Dr. Schramm said that the direct application of an ice-bag without the interposition of cloth is usually responsible for the development of cutaneous sloughing. In his case this was undoubtedly the cause. Heavy ice-bags, however, should be avoided, especially in stout people. If there is question of an operation to be performed later on in the course of the case, as for example in appendicitis, then special care must be taken that the resistive vitality of the tissues, through which the operative incision must be made, is not too much lowered by the application of an ice-bag.

Gelatin for Hemorrhage.—Dr. Schramm said that in his case of typhoid fever when the

hemorrhage seemed serious, the patient was put on an exclusively gelatin diet. Before the occurrence of the hemorrhage there had been some uneasiness, some additional abdominal tenderness and some depression. If the preliminary symptoms of a hemorrhage could be recognized with any reasonable certainty it is possible that the use of gelatin as an exclusive article of diet might either prevent the occurrence of a hemorrhage or lessen its intensity very considerably. Gelatin used in this way as an internal hemostatic has not been tried sufficiently to enable us to say with certainty whether it does good or not. We are so helpless, however, in the presence of severe intestinal hemorrhage that it seems well worth the while to try this means as effectually as possible.

Injections of Gelatin.—Dr. Lilienthal said that injections of gelatin into the circulation seemed undoubtedly to produce greater coagulability of the blood. This had been demonstrated experimentally on animals and also in the treatment of aneurism in human beings. The question of injections of gelatin for hemorrhage from a typhoid ulcer has not as yet been considered. It seems well to remember, however, that we have such a means at our command in these often alarming cases and to make use of it when occasion requires until we learn whether it is efficacious or not.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 7, 1901.

The Vice-President, Charles L. Dana, M.D., in the Chair.

The scientific business of the evening consisted of a discussion on alcoholism, its etiology, pathology, therapeutics and legal regulation.

Statistics of Alcoholism.—In the absence of Professor Chittenden of Yale University Medical School, the discussion was opened by Dr. Charles L. Dana who gave the details of his personal experience with alcoholic patients. Of those who form the alcoholic habit, or become the victims of the disease of inebriety two-thirds of the patients contract the habit before they are twenty years of age. Practically all of those who become inebriates show marked symptoms of their condition before they are thirty. It a man has been abstinent until thirty, there is very little danger of his contracting the alcoholic habit afterwards unless some special condition develops to modify his will power and alter his constitutional habit.

Neurotic Basis.—The most prominent factor in the production of inebriety is very evidently a family heredity of neurotic character. Neurasthenia is one of the prominent traits of all periodical drunkards. This neurasthenia is sometimes due to the alcoholism. It is always increased by the alcoholism. Under ordinary circumstances a drunkard will live about twenty years after his habit of drinking to excess occasionally has been established. The sot, or chronic inebriate, who is nearly always besotted with alcohol will live fifteen years or less. Death is usually due to some complication and not to the habit itself. Pneumonia, meningitis, or delirium tremens ends the scene. These affections, of course, often carry off a patient long before the term of fifteen or twenty years is past.

Number of Drunks.—An interesting consideration is how many times the human system will stand being drunk. In a recent case under Dr. Dana's care the man confessed that he had been drunk about twice a day for three years. This would make about 2,000 drunks. From his condition it might be judged that he would live for another year and that his limit would be about 3,000. A consideration of a number of other cases seems to show that 3,000 intoxications represent about the maximum number that the human organism will stand.

Types of Intoxicants.—In about one-third of the cases inebriates seem to become intoxicated on spirituous liquor alone. In about one-half the cases a mixture of spirituous and malt liquors—whisky with beer; in about one-sixth of the cases inebriates become intoxicated on beer alone. This last part of the statistics shows that beer is not a safe form of indulgence in liquor, though it is usually considered to be so. Dr. Dana has met with no wine inebriates. The people who drink wine in considerable quantities come from countries where intoxication is practically unknown and they very seldom drink even the stronger wines to excess. An exception must be made, however, in the matter of champagne. There are champagne inebriates. The maximum amount of liquor that a man can take and survive would seem to be about 3,000 gallons of whisky. With this amount the inebriate's climacteric is reached.

Legal Regulation of Inebriates.—In this State there are no effective laws that enable one to deal in a satisfactory way with inebriates. There is no doubt that habitual drunkards need restraint to enable them to keep away from liquor until their physical condition is improved enough to make it possible for them to resist their morbid cravings. The important question that must be considered is how can this legislation which is greatly needed be obtained without any infringement of the rights of the individual.

Pathology of Moderate Drinking.—Dr. Hermann Biggs said it was a very difficult thing to define moderate drinking. Individual tolerance for alcohol varies within very wide limits. Every one who has had hospital experience in New York, knows that a great change has come over the character of the patients suffering from alcoholism who are admitted to the city hospitals.

Twenty years ago, it was a very common thing to see cirrhosis of the liver. Cirrhotic changes of other kinds were not uncommon. Practically all the drunkards at that time became intoxicated by large quantities of spirituous liquors. Ten to fifteen, sometimes twenty, glasses of strong liquor were taken in the day. In the last fifteen years particularly, this has been changed. It is now the exception to find a history of the exclusive drinking of strong liquor. Not cirrhosis, but certain degenerative effects of the alcohol are now seen. Patients now say that while they take from three to five glasses of whisky in the day, they also drink from three to five pints of beer. Nearly always both forms of liquor are taken, though occasionally patients have taken only malt liquors.

Modification of Symptoms.—As the result of the changes in the habits of patients, the symptoms that come under observation have also changed. As the result of fatty degeneration, the symptoms usually seen come from the heart or the blood vessels.

The kidneys are much oftener affected than used to be the case. The records of the Department of Health form an interesting commentary on the change that has come over the habits of patients with regard to alcohol and the difference in pathological results. With regard to alcoholism, cirrhosis of the liver and hepatitis, only a small increase in the number of deaths have been reported during the last seven years. Needless to say there has been in the meantime a large increase in the population of the city. Not only this but better methods of diagnosis have made liver diseases better known to physicians. There are only three forms of disease in which there was an increase in the death rate in the city in the last twenty years. These three types of disease are the various forms of heart disease, kidney disease and malignant disease. While other forms of disease have decreased not alone in their general average, but also in absolute number these types of disease have increased very markedly. From myocarditis for instance, there are 150 per cent. more deaths than used to occur twenty years ago, although the population of the city has increased only from fifty to sixty per cent. The deaths from kidney disease have almost doubled during this period. Hospital experience is especially striking in this matter. The same phenomenon has been noticed in Berlin. It forms an interesting complement to the observations here in New York.

Alcohol and Nervous Diseases.—Dr. M. Allen Starr said that the subject of nervous diseases and alcoholism is a very large one and only one feature of it seems worthy of discussion just now. In writing about alcoholism not enough stress is laid on the varying effects of the different forms of intoxicating liquor that are used. A great deal is said about the effect of alcohol, but not enough distinction is made as to the wines and beer and the spirituous liquors. It is well known how differently wines of various kinds act on individuals. Sherry, for instance, is distinctly irritating to the temper and is apt to make the guests at a dinner party of a quarrelsome disposition. Port is much more soothing in its effect, it is more agreeable too at dinner parties, causes less discussion and controversy. Champagne is exhilarating. It has a stimulating influence on the flow of thought, it loosens the tongue, it is good for dinners where there is to be after-dinner speaking. Burgundy makes people think more slowly. It does not add to the conviviality of a festive occasion, things are apt to drag towards the end of the dinner where much Burgundy has been taken. Whisky, brandy and gin act very differently on different individuals. One should not speak then of the effects of alcohol, but of the different combinations of alcohol. The special kind of tipple to which a man is most addicted must be taken into account in considering what effect drinking has on his nervous system. It is important therefore always to ask a patient of what special form of spirituous liquor he takes most.

Action on Spinal Cord.—This action of alcoholic liquor on the spinal cord is very different from that produced on the brain. So far as is known no specific alcoholic disease of the cord is produced either pathologically or experimentally. We know alcoholic neuritis very well. Alcoholic brain lesions have been studied, but no specific alcoholic conditions of the cord. It affects both ends of the nervous system, central and peripheral, but not the intermediate conductor tracts. Alcohol affects the most highly organized nerve centers and sets up in them a process of dissolution. It acts just the reverse of evolution on the nervous system—attacking the most highly developed parts first. The lower centers of the brain and cord are not affected until later.

Pathological Studies.—Berkeley of Johns Hopkins has made an excellent set of studies of the pathological processes that are set up in the central nervous system. A characteristic lesion seems to be the destruction of the finer gemmules which exist on the terminal branches of the larger dendrites of the cerebral neurons. Berkeley's preparations show distinctly that alcohol breaks up these dendritic terminal fibers. As the result of the loss of these, cellular coordination is rendered incomplete and so there is a loss of memory and a loss of the connection of ideas. These two symptoms are characteristic of advanced stages of alcoholism clinically and the basis for the symptom is now clear.

Treatment.—It is well agreed now that the best treatment for acute alcoholism is the employment of hypodermics of strychnine and atropine. Delirium tremens is really a state

of starvation. The best treatment is to feed the individual. In the meantime his natural forces must be kept up by the use of the strong stimulants mentioned. The treatment of the chronic alcoholic or dipsomaniac is a extremely difficult question. It is probable that there is no complete recovery from periodical inebriety of a marked type with entire intermissions in which absolutely no liquor is taken. The basis of the disease is probably a moral obliquity rather than insanity. To make the diagnosis of insanity on a single symptom is always rash.

Legal Regulation.—Revision of the laws is needed that will enable one to control individuals who are given to inebriety. Once the alcoholic habit is formed, restraint is needed so that the patients can not get alcohol until their physical condition has been improved sufficiently to enable them to resist with more show of success. Under the influence of restraint there seems no doubt that one could increase the interval during which there is no drinking and so put off the evil day of the inebriate period and save suffering.

Moral suasion is of more influence than medicine. There is no doubt that neurasthenia is the basis of the alcoholic habit and that hereditary elements enter into it. With better health there is better resistance. The influence of the human will, however, is the best therapeutic agent that can be employed. There is no institution in this country to which a patient can go where alcohol may not easily be obtained. Dr. Starr makes this assertion deliberately. There should be an institution surrounded by the same restraints as for the commitment of the insane, in which an inebriate could be confined for from six months to a year, and in which no alcohol could possibly be obtained.

One may hope thus to save a certain number of inebriates and an effort in this direction is well worth the while.

Statistics Untrustworthy.—Dr. Alexander Lambert said that in the making of statistics it is not well to credit the statements of inebriates. The types of alcoholism that are interesting at Bellevue are, first, the ordinary drinker who goes on an acute drunk on Saturday night or Christmas or Fourth of July. Second, the periodic inebriate. Third, the acute alcoholic suffering from *mania a potu* which is quite different from delirium tremens. It is more manical and more furious, but there is less of terror in it. Patients get up and argue with their delusions, but without the horrors characteristic of ordinary delirium tremens and then there is rapid recovery.

Delirium tremens often develops after the alcohol is stopped suddenly. Patients sometimes come in and say that it is the water they have been drinking since giving up liquor which causes their delirium tremens. This is also the reason why delirium tremens develops so frequently after accidents. Patients confined to the hospitals are unable to obtain whisky in the amounts they are accustomed to and so the nervous explosion of the delirium tremens occurs. More than one-half the cases that come to the alcoholic wards of Bellevue are sent from the fracture wards. The relation of abstinence from liquor to their acute alcoholic condition is evident.

Moral Suasion.—At Bellevue when chronic alcoholics are sober enough to go out they are allowed to leave the hospital. When they are drunk enough to be sent to the hospital once more they are readmitted. Very little serious effort at reformation is made. Last year Dr. Lambert attempted to find out what the threat of the workhouse would accomplish as a restraint against relapses into alcoholism. For six weeks, from the middle of June, to the middle of August every patient known to be a chronic alcoholic was threatened with the workhouse if he should return. During these six weeks 481 cases were admitted to the hospital, 60 of them being repeaters. During the six weeks following only 320 were admitted, twelve of whom were repeaters. During the first six weeks there were admitted into the female alcoholic ward 161 patients. Here no threats were made and the following six weeks there were 181 patients, so that the time of the year had nothing to do with the decrease of admissions in the male ward. As soon as it was learned that the workhouse threat would not be carried out the number of admissions ran up again.

Difficulty of Cure.—Cure is almost hopeless in these cases. Nearly all of the chronic alcoholics who come to Bellevue have gone through inebriate asylums and institutions that claim to have methods of curing inebriety. Patients can not be convinced themselves that they will get over their habit, hence there is no permanent improvement. There is no doubt that there should be some legal regulation by which patients can be held in physical durance until their brain regains its vigor and their nervous system is toned up so as to help them resist temptation. Without some such means as this all ordinary therapeutic methods physical and moral are almost sure to fail.

Heredity.—It is hard to say how much heredity has to do with the inebriety. Alcoholic patients are not consciously untruthful, but they practically never tell the truth. They do not lie, but they have lost their moral sense with regard to the statement of facts. There is no doubt that alcoholism in the parents produces neurotic tendencies in the children. They do not directly inherit their inebriety, but a lack of resistance to external influences. The prognosis of a case of inebriety is hopeless unless there is some possibility of restraint.

Pathological Lesions in Nerve Cells.—Dr. James Ewing said that many changes occur in the nervous system as the result of alcohol-

ism, but the specific lesion of alcohol may be said to consist in changes in the ganglion cells. There are two forms of alcoholism, the acute and the chronic. After delirium tremens there is a specific condition of the brain visible even to the naked eye. This consists of venous congestion often to an extreme degree with marked edema. Where this condition has prevailed for some time, the nerve cells show characteristic changes. With the Nissl staining method these changes can be seen very clearly. They consist of a most violent disturbance of the economy of the cell, such as is found only in sunstroke, tetanus, and hydrophobia. As a matter of fact it is impossible to differentiate the cells of the brain which have been affected by these four fulminant conditions.

By the Nissl staining method each cell is seen to contain in health a considerable amount of chromatic substance. This is generally conceded now to contain the reserve nutriment for the cell. After death from acute alcoholism the chromophilic bodies are found to be consumed. In some cases no trace of them at all is left, in others only slight traces are found. The distribution of the lesion of the cells shows the general effect of the alcohol on the nervous system. Its influence is not limited to any one locality, but affects every part of the brain. In the motor cortex which presides over the control of the muscles, in the frontal lobe which contain the psychic centers and in other parts of the cortex there is extreme destruction of the chromatic bodies. The cells of the spinal cord do not show these degenerative changes. This confirms the observation made clinically and advanced by Dr. Starr this evening that there is no organic disease of the cord referable to alcoholism. Animals can not be successfully brought to a condition of alcoholism which will reproduce the changes that occur in human beings. This confirms the conclusion that alcohol affects only the higher centers.

General Pathology.—Alcohol is a more frequent etiological factor in the production of visceral pathological lesions than is tuberculosis or syphilis. The whole of general pathology is stamped with the effects of chronic alcoholism. The brain cells are very characteristically affected, but every cell in the body suffers from the effects of the alcoholisms.

Legal Regulation.—Dr. Joseph Collins said that the most important thing needed for the cure of alcoholism is prolonged abstinence from alcoholic liquor, which puts the nervous systems of inebriates in a condition to help them resist the constitutional craving for spirits. There must be a law to restrain alcoholics. A number of countries have such laws. The experience of New Zealand, of certain of the provinces of Australia and of Switzerland show that such laws are practicable. South Australia particularly has an effective set of legal regulations for inebriety—every one who is convicted of being drunk three times within six months being liable to commitment to an inebriate asylum. Switzerland is the only country in Europe that has such a regulation, but her experience is encouraging. As the result of the recommendations of recent Congresses France will soon have laws and institutions for inebriates.

United States Laws.—In the United States laws in this matter have been desultory and spasmodic. In New York for instance there is an inebriates' home to which alcoholics can be committed and which receives 12½ per cent. of the money obtained from licenses, yet its power for good is dying out. There is at Inwood St. Saviour's Home conducted by the Episcopal Sisters to which women may be committed who are addicted to the alcoholic or any of the drug habits. In other States there are corresponding institutions, but somehow their efficacy is not what it could and should be.

Alcohol and Tuberculosis.—Dr. Knopf said that alcohol is one of the greatest etiological factors in the development of tuberculosis. Twenty-five per cent. of the scrofulous children are born of tuberculous parents. Alcohol is also frequently phthisiogenetic in the adult. Doctors frequently mislead patients by recommending the use of alcohol freely and making them think that it is a specific for their disease. Not infrequently Dr. Knopf has been told by patients that they thought it the best thing for them. Alcohol is undoubtedly useful in phthisis, but it may easily disturb the nutrition and if used for its antipyretic influence will usually make the patients alcoholic habitues. If there were better tenement houses, if men could go home to agreeable living apartments, if their wives were good cooks, there would be less alcoholism and much less tuberculosis. Without an intelligent wife and a cheerful home alcoholism will surely increase.

Harmfulness of Moderate Drinking.—Dr. George Peabody said that it is wonderful what an amount of ignorance exists with regard to the effect of alcohol on the system. This is true even for the well informed. How often does not the doctor hear it said that a patient has surely not injured himself by taking alcohol because he has never gotten drunk. Drunkenness is only a social incident. Alcohol may work its worst harm on the system without producing drunkenness. It must be remembered that the distilling and the brewing companies represent enormous investments the main purpose of which is to keep up the sale of intoxicating liquor. These immense financial interests are practically banded together to debauch the community. These make legislation difficult. Besides these there are other favoring factors sometimes unthought of. Many of the so-called chronic remedies and certain of the stimulant

bitters, are really only diluted alcohol. Some years ago the Massachusetts Board of Health analyzed twenty to thirty samples of bitters that were advertised as containing no alcohol. Some of them contained as high as 40 per cent. of alcohol. This is, they were practically whisky. They were advertised as soothing inducements to temperance.

Wine-Bibbing.—When the patients say that they take wine it must not at once be concluded that they take a mild form of liquor. Sherry for instance is a popular drink, but it is not wine in any true sense of the word. To the natural wine is always added spirits in varying proportions, so that some kinds are as strong as whisky. Women will often take a glass of sherry who would not think of drinking whisky.

Dr. R. H. M. Sells said that "Vinegar Bitters," so much advertised as a temperance drink, contained almost as much alcohol as whisky. The sum of $1,200,000,000 was spent last year on alcohol; $6,000,000 on missionaries—Keeley himself died of alcoholism so that so-called cures are mainly "fakes."

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 11, 1901.

The President, Robert F. Weir, M.D., in the Chair.

Diet in Treatment of Heart Affections.—Dr. Henry Illoway read a paper on this subject. He said that while all the treatises on cardiac diseases referred to the importance of such a regimen, the information given was of a general character, and the necessity of correct dietary rules was not appreciated. That the stomach has a marked influence upon the heart had long been recognized, angina pectoris and even cardiac dilatation have been known to result from gastric disturbance.

Details of three cases were given. The first was that of a woman of fifty-seven years suffering from dilatation, with frequent paroxysms, attended by a sense of agonizing fear. The trouble was primarily due to nervous shock. Her weight, originally 175 pounds, became reduced to 100, notwithstanding that she was a very hearty eater and indulged in all sorts of dietary excesses, even between her meals. She was treated by the best physicians, and finally her case was given up as hopeless. When first seen by Dr. Illoway she spent all her time between her bed and her lounge, with brief intervals in a rocking-chair. He explained to her that she was in no real danger, and encouraged her to move about and get the air. A strictly regulated diet was enforced, and she was treated with tonics (particularly nux vomica and arsenic), and with systematic massage. The paroxysms entirely disappeared, and she is now in excellent health.

The second case was that of a clerk suffering from aortic stenosis and mitral regurgitation, who was incapacitated for work. Diarrhea was a prominent symptom. All meats, all fruits, and all vegetables were withdrawn. The diet prescribed consisted of eggs, milk, crackers, and animal broths, in limited quantities, with a little old sherry at bedtime. Medical treatment was given *pro re nata*, and consisted principally of strophanthus and iron. Under this course he rapidly improved, so that he was enabled to resume his work.

The third case was that of a pharmacist of twenty-six years, with tricuspid regurgitation. He suffered greatly from pain in the chest, with shortness of breath, and had the appearance of a tuberculous person. He had, in fact, been treated for this disease, although there was no cough. He was advised to give up the cares of business, to go to the country, not to lift or carry, and to avoid stairs. The diet prescribed was almost the counterpart of that of the preceding case, and he improved very rapidly. After a time he felt so well that he concluded to return to the city. He opened a new store and was soon engrossed with the cares of a large business, while he indulged his appetite freely. The heart could not stand this strain, and he broke down again. The damage sustained was now irretrievable, and, while he improved for a time under treatment, he finally died with symptoms of cerebral congestion.

Gastro-Intestinal Affections and the Heart.—Dr. L. F. Bishop said that many cases of gastric and hepatic disturbance are of cardiac origin. He cited a case of myocarditis in which the patient, a young woman, was treated for malaria, gastro-enteritis, etc., without success. She was then sent to St. Luke's Hospital, where her stomach was washed out and she was given calomel, with anodynes to relieve her pain. She finally left in disgust. When she came under Dr. Bishop's care he put her to bed and treated her principally with digitalis and a little hydrochloric acid. The venous engorgement of the stomach and liver were promptly relieved when the heart's functions were restored, and she was soon going about in comparatively good health. As a rule affections of the stomach are secondary to those of the heart, rather than the reverse. Notwithstanding all that has been said on the subject of diet it is not possible to lay down fixed rules, and each individual instance must be considered by itself. A judiciously mixed diet, at rather frequent intervals, was generally the most satisfactory. He certainly saw a great many more cases of disease of the heart's muscle now than formerly. There is great risk from any overloading of the stomach or attacks of indigestion, and therefore indiscretions in diet are particularly dangerous for those suffering from cardiac disease.

Diet Not More Paramount in Cardiac Than

in Other Diseases.—Dr. F. W. Jackson disagreed with Dr. Illoway's conclusions, and thought that mistakes in diet were made as well as in medication. In some instances hygiene and diet are of the greatest possible importance, while in others they are of no consequence. Of course, if certain forms of food give rise to disturbance, it is essential to regulate the diet.

Definite Dietary Rules of Great Advantage.—Dr. Alexander Lambert thought the profession owed a debt of gratitude to Dr. Illoway for giving definite rules, as the books were certainly altogether too vague on this subject. People usually eat too much. Eventually the arteries or the myocardium tell the story, and it becomes necessary to seek medical advice. It is very difficult, however, to fight against the habits of a life-time. Especially is this true for the gouty subjects. In case of angina pectoris the patient should take his meals dry, and four hours should be allowed for digestion, with an additional hour for the stomach to rest. At the end of four hours after a meal water or tea may be taken, and the liquid should be hot rather than cold. Food between meals should be absolutely prohibited. The principal meal should always be in the middle of the day. More than five ounces of fluid should never be taken at any one time. Alcohol is not required, but if it is insisted upon, one-half ounce of whiskey in the twenty-four hours is ample. The cutting off of all tobacco is absolutely essential.

Diet First in Importance.—Dr. W. H. Porter said he did not think diet should be divorced from medication. With the present knowledge the subject of dietetics is not as difficult or intricate as it formerly was. The system requires about equal proportions of starch, proteid matter, and fat, and the problem is how to get the proper amount of each appropriated with the least taxation. There should therefore be a well-regulated mixed diet, but one in which animal food predominates. The following list is suggested. Two eggs, seven ounces of wheat bread, with butter, and from half a pound to a pound of meat. The stomach is not the only organ of digestion. As a matter of fact only one-ninth part of the digestion is performed in this organ, while the other eight-ninths belong to the intestines. A careful watch of the urine will always tell how the patient is doing. If the amount of urea is low and of the uric acid large, the condition is unsatisfactory, while the presence of indican indicates indigestion. Dr. Porter had never found it necessary to put this class of patients on an absolutely liquid diet.

Anesthetization as a Specialty.—The second paper of the evening was by Dr. S. Ormond Goldan. It was to be remembered that as the result of an operation the patient was liable to suffer not only from surgical shock, but also from anesthetic shock. Hence it was often of vital importance that the latter should be minimized to the greatest possible degree. In order to accomplish this the anesthetic given should be selected with the greatest care and administered with the highest skill, and this could best be done by one who had devoted special attention to the subject. Safety was of the first importance, and it was a well-known fact that fatalities had sometimes resulted from operations of the most trifling character. The specialist was always prepared for any emergency that might occur. In order that anesthesia could be secured with the greatest success, as well as safety, it was desirable that a careful examination should be made of the patient a considerable time preceding the operation and again immediately before the latter.

MEDICAL SOCIETY OF RUSH COLLEGE.

Stated Meeting, Held March 4, 1901.

Acute Ulcerative Endocarditis.—Dr. Theodore Tieken demonstrated this specimen showing a large perforation in the posterior segment of the aortic valve, and almost complete destruction of the anterior cusp by the ulcerative process. The valves were covered with large vegetations, many of which were calcified. The mitral valves were likewise studded with vegetations, which extended down the chordæ tendineæ as far as the apex of the papillary muscles. In addition to the ulcerative process on the aortic valves, an area of ulceration was found at the attachments of the bases of the semilunar valves, which extended through the walls of the aorta, into the peri-aortic space. The heart was greatly hypertrophied and showed some interstitial fibroid changes. In the same case were found an annular pancreas and a sacculation of the duodenum, caused by the constriction of the intestinal lumen by a band of glandular substances, springing from the head of the pancreas in such a manner as to entirely encircle the lower part of the duodenum (descending portion) forming a true "pancreas annulare." The pancreas was normal in size and consistency, and cut with about normal resistance. The head measured 4 cm. in its vertical and 3½ cm. in its transverse diameter. The annular portion measured 2¾ cm. at its narrowest portion and was 1 cm. in thickness. The ducts were in every way normal, and no abnormality was noticed in its vascular supply. In a hurried review of the literature he was able to find only four other cases reported to date. Although the patient had been under observation for nearly a year, no symptoms referring to the gastro-intestinal tract were ever manifested during life.

Obstruction of Popliteal Artery.—Dr. James B. Herrick presented a specimen showing obstruction at the bifurcation of the pop-

liteal artery produced by an embolus from the heart, the seat of chronic valvular and myocardial disease. He also showed a specimen of a suprarenal tumor where the tumor mass had invaded the inferior vena cava. This finding, which had been suspected during life, explained the early occurrence of an edema of the lower extremities and had been one determining factor in deciding against operation for the removal of the kidney.

Lymphatic Leucemia.—Dr. Herrick also showed specimens of blood from six cases of lymphatic leucemia. He referred to the unknown etiology of the disease, to its clinical separation into acute and chronic varieties, to the resemblance of the former to an acute infection and of the latter to Hodgkin's disease, and also dwelt upon the variations in the blood picture as shown in his six cases. The statement so frequently made that in lymphatic leucemia nucleated red corpuscles are very rare, was disproven in four of the six cases, three acute and one chronic, and specimens were exhibited showing numerous nucleated red blood corpuscles. He spoke also of the great variety in the picture presented by the blood according as the larger or smaller mononuclear forms prevailed in a given case. In one case, a rapidly acute one, there had been about two per cent. of myelocytes. Another interesting combination he had seen was that of a patient with carcinoma of the neck and jaw with diffuse hyperplastic enlargement of the lymph glands and with the typical findings of a lymphatic leucemia, the blood counts never showing less than 100,000 leucocytes.

Aneurismal Extension.—Dr. L. Hektoen presented several specimens illustrating interparietal and intraparietal extension into the heart of aneurism of the beginning of the aorta, and of dissecting aneurism of the heart. He described the spatium periaorticum cordis of Vestberg. The spatium periaorticum cordis is situated at the root of the aorta and is covered by the reflection of the epicardium as it passes over the aorta behind the auricles and forms the floor of the sinus transversus pericardii. It is in this space that interparietal dissecting aneurisms of the heart most frequently are found by rupture or ulceration of its internal wall, the aorta. The specimens demonstrated illustrated the formation of dissecting aneurism in this space as a consequence of ulcerative endocarditis of the aortic valves, and in consequence of the rupture into the space of small aneurisms in the beginning of the aorta developing primarily upon the basis of a syphilitic aortitis. He also demonstrated a specimen of a large interparietal aneurism in the right ventricle originating in the sinus Valsalva of the aorta, and also an aneurism originating in the left ventricle by two small openings and forming a large cavity upon the lateral and posterior aspects of the left ventricle. The postmortem in this case was made by Dr. LeCount and the question as to the dissecting character of this aneurism was discussed, the conclusion reached being that the aneurism most likely originated in a suppurative process in the myocardium and probably reached its present large extent in consequence of more or less dissection of the walls of the left ventricle.

Portal Obstruction.—D. H. G. Wells reported two cases illustrating the relief of portal obstruction in hepatic cirrhosis by plastic peritonitis. In one the condition was found at autopsy, there having been no evidence of obstruction during life; the numerous adhesions of a chronic fibrous peritonitis were found largely replaced by thin-walled vessels, full of venous blood, up to the size of a crow's quill. The portal obstruction was due to an obstructive biliary cirrhosis from impaction of a calculus in the common bile-duct. The other case was that of a man with excessive ascites of about twenty months' duration, requiring frequent tapping, and due to alcoholic atrophic cirrhosis. A large umbilical hernia, resulting from the ascites, became strangulated and was reduced by operation. No attempt was made to establish a plastic peritonitis and there was but little intra-abdominal manipulation, yet the ascites never recurred up to the time of the patient's death, eleven months later, from carcinoma of the pharynx.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held March 11, 1901.

President, L. Hektoen, M.D., in the Chair.

Primitive Splenomegaly.—Dr. Maximilian Herzog read this paper, based upon a study of the literature of the subject and on two cases in which Dr. M. L. Harris had performed splenectomy (See Medical News, p. 471).

In the discussion Dr. W. A. Evans referred to a patient of Dr. Ferguson in whom there occurred petechial spots in the skin and the spleen became smaller before death. He spoke of a case reported by Dr. Dalton before the London Clinical Society, which was clinically one of splenic anemia, but at autopsy the enlargement of the spleen was discovered to depend upon passive congestion, due to constriction by an anomalous colon.

Dr. Leo Loeb declined to accept the theory of an enzyme which destroys the red blood-cells in the spleen. Dr. E. H. Ochsner referred to a case which clinically was splenic anemia, and which improved for a time after the spleen was removed, but subsequently died. A few small peritracheal glands, which were tuberculous, were found at autopsy. A possible infection in such cases must always be considered. Dr. B. W. Sippy spoke of the similarity of these cases to the ordinary lymphatic pseudoleucemia as regards blood

changes, general asthenia, etc., a similar enlargement of the syleen also being observed. In many cases of splenic anemia there is enlargement of the lymph glands, although it may be slight. In all cases the bone marrow has been converted into a fetal condition, like that found in many cases of pseudoleucemia lymphatica. He objected to the term splenic anemia, and considers the one splenic pseudoleucemia to be the proper one. He believes the primary cause cannot be positively located in the enlargement of the spleen. In the case described by himself, the fibrous changes were much more marked than in Dr. Herzog's. This he thinks may depend upon the longer duration of the disease.

Dr. Herzog in closing said that he did not claim that there was proliferation of the endothelium alone, but that the increase in the endothelium was enormous, so much so that the condition had been mistaken for an endothelioma. Dalton's case had not been considered as it was too indefinite. One reason for separating these cases from lymphatic pseudoleucemia is because they are curable by operation.

Dr. Theo. Tieken exhibited a specimen of pancreas annulare, with resulting constriction of the duodenum so that a large fusiform sacculation of the latter had formed.

Dr. H. M. Ricketts presented specimens of experimental general blastomycosis in the dog produced by the intravenous inoculation of an organism obtained from a case of blastomycosis of the human skin.

BOOK REVIEWS.

Introduction to the Study of Medicine. By G. H. Roger, M.D. Authorized Translation by M. S. Gabriel, M.D. D. Appleton & Co., New York.

This book is intended to give medical students at the beginning of their study not only some elementary technical knowledge of disease, but also some conception of what disease is, how it originates, what the reaction of the organism is, and how a physician studies, places, and treats any particular disease.

The style is rather diffuse, especially so for a book which in five hundred and thirty-six pages aims to give a superficial familiarity with all medicine. Some chapters go into minutiæ which can hardly be of service to those for whom the book is intended. For example, there is a long account of the classification, the names, and the cultural characteristics of moulds and bacteria, which is, however, not full enough for practical use. Certain chapters giving a detailed description of the effects of some external causes of disease, such as cold, heat, and electricity, may be found entertaining and instructive for the experienced graduate.

Prof. Roger tends to depreciate the practical use of the clinical laboratory and to assert the sufficiency of simple bedside observation.

Diseases of the Anus and Rectum. By D. H. Goodsall, F.R.C.S., and W. Ernest Miles, F. R. C. S. Part I. Longmans, Green & Co., London and New York, 1900.

This is the first of two volumes on this subject and contains a very good resumé of English opinion with regard to the diseases of the lower end of the digestive tract. The question of ano-rectal fistula is treated with special completeness. The illustrations of this subject are numerous, but many of them fail to convey any additional information to what is contained in the text. The reproduction of photographs of the anal region is not apt to prove good material for illuminative illustration. The authors are reasonably conservative with regard to operations for fistulæ, yet we think the modern trend of thought with regard to the opening of tuberculous abscesses is sufficient to justify even greater conservatism than the authors might think proper. Most ischio-rectal collections of pus are what may be called cold abscesses and these we have learned Nature can take care of as a rule almost better than the surgeon. The chapter on hemorrhoids is the longest in the book and the methods of physical examination and the possible medical treatment of the condition are well written up.

Physiological Optics, Dioptics of the Eye, Functions of the Retina, Ocular Movements and Binocular Vision. By Dr. M. Tscherning, Adjunct-Director of the Laboratory of Ophthalmology at the Sorbonne, Paris. Authorized Translation by Carl Weiland, M.D. The Keystone, Philadelphia.

An essential feature of a complete work of this kind is the opening chapter on *optic principles;* but the interest and helpfulness of the book are not found here. It is to be found in the subsequent chapters, especially those dealing with anomalies of refraction, spherical aberration, entopic phenomena, accommodation, color sense, and ocular movements. Especially valuable is the chapter on accommodation in which a new putting of things and new illustrations make the subject matter very helpful to the understanding. Indeed, there is none of the book superfluous. There is special need for it, because ordinary treatises cannot in the nature of things go into full consideration of each of these subjects. Here they receive a scientific and full treatment up to date which makes the book an authority for students and specialists. None could more suitably give us the translation of this valuable work than could the distinguished gentleman whose own name is associated with much work of the same character.

ORIGINAL ARTICLES.

THE IMMEDIATE AND REMOTE RESULTS IN ONE HUNDRED CONSERVATIVE OPERATIONS ON THE OVARIES AND TUBES; WITH BRIEF REPORTS OF FOUR CASES.[1]

BY W. L. BURRAGE, M.D.,
OF BOSTON.

YOUR chairman has been kind enough to invite me to give you the results of my experience in operating on the uterine appendages with a view to the preservation of their function. As I told him at the time he extended the invitation, I am always glad of an excuse for coming to New York. We in Boston regard the metropolis as a Mecca to which we must periodically journey in search not only of entertainment and amusement, but of all that is new and progressive in medicine, and I hope to profit largely by the discussion of the subject of this evening.

Last May I read a statistical paper on the "Remote Results of Conservative Operations on the Ovaries and Tubes" before the American Gynecological Society. This paper embodied a tabulated report of 85 cases which had been under observation a year or more since their operations, as it seemed to me that at least a year after operation was necessary in order to arrive at just conclusions as to end results.

Classing as conservative operations all those in which, an operation on the appendages being performed, not including cases of hysterectomy or suspension of the ovaries, one ovary, a portion of one ovary, or one tube or a portion of one tube was left behind, my cases up to March 1, 1900, numbered 137. Between March 1st and February 1st, I have had 19 additional cases to add to my list making a total of 156. Of these, 100 have now been under observation for at least a year after their operations.

It is my purpose to-night to present a résumé of the immediate and remote results in these one hundred cases and also to report a few illustrative cases.

The different points in the technic I shall omit from my paper, also the indications for performing conservative operations.

The Immediate Results.—Three patients out of 156 have died as a result of operation; one, a case of colpotomy in which there was a secondary hemorrhage, my only case of the kind; the second, a case of neglected and septic ectopic pregnancy, in which I made an error of judgment in resecting the remaining ovary and tube, and the third, a case of multiple operations for adherent retroversion with salpingitis and appendicitis, and ulceration of the bladder on a patient who, unknown to me, was very much debilitated at the time of operation. In these cases, in order to treat the ulcerated bladder, I exceeded my customary rule of finishing all operations within two hours. The patient died of shock in thirty-six hours.

Among my early operations, certain of the patients had marked enlargement of a resected ovary in the weeks immediately following operation, the enlargement disappearing in the course of time. Some of the patients had a good deal of pain. Latterly these phenomena have been noted less frequently, and I am inclined to think that the enlargement and pain were due to free puncturing of cysts without especially careful measures to produce hemostasis, and that the enlargement and pain were caused by hemorrhage as well as by trauma.

Pelvic inflammatory exudate about ovary and tube has been noted in a few cases following resection of a closed tube, these being in the old gonorrheal cases as far as could be determined, at all events in those patients who had had repeated attacks of pelvic inflammation previous to operation.

In other respects the convalescence from operation has been as uneventful as in other similar operations where ovaries and tubes had not been resected.

We must recognize the fact that as a general rule conservative operations require a somewhat longer time for their performance than the radical operations, and it is important to bear this in mind when operating on enfeebled patients. My rule in performing all multiple operations is to do nothing more than can be well done in two hours at the outside from the first incision to the tying of the last suture, the patient being carefully prepared and in good condition before the operation. A large majority of this class of operations, which includes the conservative operations, are finished and the patient in bed inside of an hour and a half. The total length of time a patient is under ether is in my opinion of more importance than the time taken in removing any given tumor.

The Remote Results.—The greatest interest centers in the late results of the preservation of ovarian and tubal tissue. We are all en-

[1] Read before the New York Academy of Medicine, February 7, 1901.

gaged in the determination of the value of leaving an ovary or part of an ovary when it is necessary to do hysterectomy, as in the case of fibroids. In the few instances in which I have followed this plan the symptoms of the artificially induced menopause have seemed to be lessened. We must entertain the possibility of pregnancy occurring in the Fallopian tube or in the abdominal cavity where the uterus has been removed and ovary and tube are left. An instance of this has already been reported in literature.

To summarize the statistics presented in my paper of last May and also the statistics of fifteen additional cases which have been collected since then, it appears that symptomatic cure was recorded in 73 out of 100 cases and 27 were not relieved. From the fact that a large number of the patients were pronounced neurasthenics, and from the inherent difficulty in determining in this class of cases the relative causative effect of disease of the uterine organs and disease of the nervous system on the symptoms presented in a given case, we are not to attach too much weight to these figures. The data are all from my private notes taken with the purpose of reporting the results, and a large majority of the patients have been under my personal observation.

Anatomical cure (ovaries and tubes normal to feel and well placed) was noted in 44 out of 69 cases who came under observation, or 64 per cent. Some enlargement or prolapse of ovaries and tubes was found in the remaining 25 cases. Pregnancy following operation occurred in 19 cases. In no instance, however, did pregnancy result after the resection of a closed tube, both tubes being closed at the time of operation.

To estimate the probability of pregnancy occurring after conservative operations on the ovaries and tubes we must deduct from the list of married women those who have been through subsequent oöphorectomies or hysterectomies, those who have become widows or have taken measures to prevent conception, and we must add those who have been married since operation. According to my list, which must of necessity be more or less inaccurate, 32.7 per cent. became pregnant. Furthermore, it is a noteworthy fact that all of the cases of subsequent pregnancy except three had had one or more pregnancies previous to operation, so that we may say that 34½ per cent. of those who had previously borne children became pregnant after operation, whereas only 6¼ per cent. of those previously sterile subsequently became pregnant.

Several of the unsuccessful cases have been women over thirty-five years old with extensive, long-standing tubal and ovarian disease; and it would seem that it is less desirable to subject such cases to conservative operations than the younger women with the same trouble, for at this time of life the patient is suffering not so much from the ovarian and tubal affection as she is from the long-continued effects of it. There is little chance that the uterine organs, diseased for many years, will be able to regain an approximately normal condition in the remaining years of functional activity, both because of the limited time and because the reparative powers of the system are less vigorous than at an earlier age. Therefore these patients either need no operation at all or they need an operation which will eliminate entirely the ovarian function, thus doing away with monthly pain and discomfort, an additional burden to an already jaded nervous system.

As bearing on the question of resected ovaries becoming diseased at some future time the following quotation from the paper already referred to embodies my views:

Out of all the 85 cases, in only one case, a syphilitic, was another operation necessary because of such subsequent enlargement of an ovary resected for cystic disease. In 3 instances in which one ovary was removed and cysts were punctured in the remaining ovary because it was cystic, another operation was required. In 7 other cases a remaining ovary, cystic at the time of operation, was later noted as being large, although causing no ovarian symptoms.

In 5 cases of the extensive purulent inflammatory type, all of them gonorrheal and 3 of them syphilitic, one ovary and tube being removed in each case, the remaining ovary became diseased following operation, and another operation was indicated, although as yet only one of these patients has actually submitted to operation.

In 2 of my early cases, both gonorrheal, a diseased ovary was left in the bottom of the pelvis, in one case after the removal of the sac of an ectopic pregnancy, and in the other after the removal of a pus tube. Both of these women have been sufferers since their operations, six and seven years ago respectively, but have not been willing to undergo another operation.

As far as I have been able to determine, the amount of ovarian tissue present has no definite relation to the amount of menstrual flow or to the intensity of sexual desire and gratification.

The most unfavorable cases for conservative operations are, in my judgment, the pronounced neurathenics who are approaching the menopause, also patients with long-standing gonorrheal infection, and those having both ovaries thoroughly riddled with cysts.

Illustrative Cases.—When it is not advisable to remove the uterus, in chronic inflammatory diseases of the appendages, especially in young women, it is best to leave some ovarian tissue, even in the presence of early tuberculosis. The following case in an instance in point:

Case I.—M. C. N., twenty-five years old, a patient of Dr. R. A. H. MacKeen of Glace Bay, Cape Breton, was referred to me April 10, 1899. The patient had been married eight years and had been sterile. Chief complaints, poor general health, indigestion, loss of weight, dysmenorrhea of increasing severity, the catamenia always irregular and coming every two or three weeks up to the time of her marriage and since then every three or four months, flow of three of four days. On the months she skipped her periods she had severe pains in the back and groins. No cough; no history of phthisis. Physical examination showed a well-developed, well-nourished woman of dark complexion, weighing about 130 pounds. The uterus was slightly enlarged and in the axis of the vagina, both ovaries and tubes being large and adherent. Abdomen soft; not especially sensitive. Heart and lungs negative.

Operations May 11, 1899. Curetting, removal of right ovary and tube, resection of left ovary and tube, suspensio uteri. By curetting a large amount of soft tissue was obtained. On opening the peritoneal cavity it was seen that the parietal peritoneum and portions of the peritoneum on loops of intestine were studded with translucent glistening bodies the size of millet seeds that felt rough to the touch. An ounce or two of free fluid in the peritoneal cavity. Both ovaries and tubes large and the ostia of the tubes closed and ovary and tube adherent to each other. Omentum large and firmly adherent to the peritoneum over the bladder and about the pelvic brim. Appendix vermiformis normal.

The adhesions were separated and bleeding points in the omentum tied and the entire right ovary and tube removed, including a small hard nodule in the structure of the tube imbedded in the uterine tissues at the cornu, a special dissection being necessary to get it out. Oozing was controlled by a continuous suture of catgut from the ovarian vessels to the uterus. The proximal three centimeters of the left tube appeared to be normal and accordingly it was not removed, no attempt being made to form a new ostium, a difficult procedure in this portion of the tube. Three-quarters of the left ovary was removed by a V-shaped incision along the outer border. A separate tie was placed on the ovarian artery and the edge of the broad ligament and the cut surface of the ovary were sewn together with a continuous lockstitch of catgut. The uterus was suspended by three sutures of chromicised catgut passed transversely through the posterior face of the fundus, the parietal peritoneum and transversalis fascia. Irrigation of the peritoneal cavity with normal salt solution, some being left in, and closure of the abdomen without drainage completed the operation.

The patient made a good convalescence and when she went home, June 14th, the uterus was well suspended and the left ovary a little larger than when it was resected.

The pathologist at the Harvard Medical School, to whom the specimens removed were submitted for examination, reported as follows: "Ovaries large, containing small cysts. Tubes convoluted, matted, enlarged to the size of the little finger, on section showing yellowish fluid. Microscopic examination of the tubes shows great proliferation of the connective tissue and mucosa and characteristic tubercle. Ovaries showed distended blood-vessels, numerous corpora and simple retention cysts. The diagnosis is tuberculosis of the tubes and chronic oophoritis."

A month ago Mrs. N. wrote me that she was enjoying the best of health. Her weight was 168 pounds, she felt well and strong, had no cough and her catamenia were regular and painless every month. I have recently had a similar statement from Dr. MacKeen as to her condition.

When the tubes are found to be open at the time of operation subsequent pregnancy is common even if only a small portion of ovary is left. The following case, which was left with one tube and a third of one ovary will serve as an example:

Case II.—D. W., twenty-five years old, married, entered my service at St. Elizabeth's Hospital October 27, 1899. She had had one child three years before and one abortion at three months, two months before. The monthly periods had been irregular since the abortion, coming every two or three weeks, lasting three to four days, and using twenty-four napkins. Chief complaints, weakness, pain in the sacral region and left groin and a bearing down sensation in the rectum. She also had incontinence of urine when the bladder was full. The uterus was retroverted in the axis of the vagina and enlarged so that the cavity measured 8 cm.; there was bilateral laceration of the cervix with eversion of the lips; the pelvic floor and perineum were lacerated to a medium extent, and both ovaries were enlarged, the left being the size of a hen's egg.

The operations consisted of curetting, trachelorrhaphy, perineorrhaphy, removal of left ovary and tube, resection of right ovary, and suspensio uteri.

On opening the abdomen both tubes were found to be normal. The left tube was so closely adherent to the left ovary, which was converted into a thin-walled cyst 5 cm. in diameter, that it was removed with its ovary. The right ovary was enlarged to twice the normal size and was full of small cysts. The outer two-thirds were removed and the edges of the rent in the remaining third brought together with a continuous lockstitch of No. 1 catgut.

The patient made a good recovery and went home in three weeks, the ovary not being dis-

tinguishable by bimannal palpation at the time of her discharge from the hospital.

She menstruated only once after getting home as she became pregnant. Her pregnancy was perfectly normal and was followed by a normal labor, and December 1, 1900, she brought her large, healthy baby to my office. At that time her uterus was in good position, well involuted and the right ovary could not be felt.

Normal pregnancy and labor following resection of the ovaries in a woman six years married and sterile, having retroversion with dense adhesions, the tubes, however, being normal, are shown in the next case.

Case III.—M. C., twenty-five years of age, was sent to me September 29, 1899, by Dr. J. P. Treanor of Dorchester, Mass. The patient was a well-developed and well-nourished woman presenting a history of phthisis and cancer on her mother's side. She had had a long persisting middle-ear catarrh two years before and had had poor general health since marriage six years before. No history of gonorrhea. Had had a vaginal discharge since eighteen years of age, yellow and irritating, and at times enough in quantity to require the use of a napkin. Further symptoms were pain in the back, irregular and profuse catamenia, poor sleep and poor digestion.

The uterus was in the third degree of retroversion and fixed and slightly enlarged. The ovaries could not well be made out. The crown of the cervix was extensively eroded, more especially front and back.

Operations December 11, 1899. Curetting, trachelorrhaphy, resection of both ovaries, and suspensio uteri. Trachelorrhaphy was performed in order to do away with the erosion. On opening the abdomen the cul-de-sac of Douglas was found to be entirely obliterated by adhesive inflammation and the ovaries and tubes were riding on top of the exudate, the right ovary being enlarged to twice the normal size and cystic, and the left ovary moderately cystic. Both tubes soft and swollen, but with ostia open. The right ovary was freed from adhesions and a third of it cut away, two cysts being enucleated from the remaining portion. Two cysts in the left ovary were punctured. The cul-de-sac was freed by a somewhat difficult dissection and the uterus suspended.

The convalescence was uneventful and the patient was sent home in three weeks. March 27, 1900, I examined her and the uterus was in place and was pregnant. Dr. Treanor telephoned me two weeks ago that Mrs. C. had had a normal pregnancy and gave birth to a healthy boy at term, the labor being entirely normal.

I will close this paper with the report of a fourth case, which, though strictly speaking not a conservative operation, the ovary being left behind in the pelvis because it could not be found, is quite unique in my experience.

Case IV.—A. H., thirty years old and married 13 years, was referred to me by Dr. E. M. Buckingham of Boston May 19, 1899. She gave the following history: Had had four children, the youngest being a year and a half, and three miscarriages. The first labor was terminated by embryotomy, the others were normal. There had been a curetting after one of the miscarriages, nothing of note as to the others. Catamenia very irregular and the flow scanty. Has been flowing a little for the last six weeks and has had constant pain in the abdomen extending down the thighs, and pain in the rectum since the flow began. Gas in the bowels increases the pain, also defecation. Loss of flesh. Patient is nervous and irritable in temper.

Physical examination showed a tall, well-developed and well-nourished woman of dark complexion. Skin of abdomen soft and wrinkled, vulva gaping, urethra dislocated downward, uterus in good position in the pelvis, somewhat enlarged, with bilateral tear of the cervix of moderate degree. A mass behind the uterus the size of a Florida orange, of irregular outline and excessively sensitive to the touch. Probable diagnosis, ectopic pregnancy with lacerated cervix and perineum and dislocation of the urethra downward.

Operations, May 25, 1899. No tissue was obtained by curetting. The cervix and perineum were repaired by rather extensive operations. On going through the thin abdominal walls dark blood was found in the peritoneal cavity; the omentum was large and thin. The mass in the cul-de-sac was made up of blood-clots and both ovaries and tubes matted together. The clots and as much of the sac of plastic lymph enclosing them as possible were removed. The left tube measured 4.5 cm. in length and 3 cm. in diameter. In its outer third was a mole of firm consistency, the walls of the tube being much distended but intact, the hemorrhage having come through the ostium abdominale of the tube. The inner third of the tube showed two little hard nodules the size of pea beans in the substance of the tube and occluding its lumen. The right ovary was converted into a cyst the size of a hen's egg and there was no good ovarian tissue which could be preserved. The right tube was enlarged, thickened, convoluted, adherent to the cyst wall, and its inner third was studded with hard nodules similar to those in the left tube. The left ovary could not be found but was thought to be incorporated in the sac of the pelvic hematocele, all of which could not be removed owing to lack of time. Both tubes and the right ovary were removed completely by cutting them away and sewing the edges of the broad ligaments over and over with chromicised catgut, making extra ties for the ovarian arteries. A small piece was taken out of the uterine tissue at each cornu of the uterus so that no tubal tissue was left behind.

The uterus was suspended to keep the fundus out of the raw surface in the cul-de-sac and to counteract the dislocation of the urethra. Salt solution was left in the peritoneal cavity and the abdomen closed without drainage.

The convalescence was interrupted by an attack of cystitis of mild grade lasting two weeks. In a month, when the patient went home there was good union in the cervix and perineum and abdominal wound, the uterus was well suspended and the cul-de-sac free.

The pathologist examined the specimens removed and reported that there were no evidences of ectopic pregnancy.

Now come the unusual features of the case. Six months after the operation a physician in a neighboring town, who was taking care of Mrs. H. at the time, telephoned me that she was two months' pregnant to the best of his judgment, and two months later the patient's husband said she had had a miscarriage. December 29, 1900, in response to my request, she came to my office and I then learned that she had had a miscarriage without doubt: she saw the fetus, which was well-formed and of the male sex, and the miscarriage had been at four months as nearly as she could calculate. Furthermore, at the time of her visit to my office, a year and a half after her operations, she had gone over her time three months, having been previously regular every month since the operation, with the exception just noted, and by examination she proved to be three months' pregnant, not a sign or symptom being lacking to the diagnosis.

We have in this case an example of pregnancy occurring twice following complete removal of both tubes and one ovary for tubal mole, chronic salpingitis and cyst of the ovary. As an explanation we have to assume that an opening became established at the uterine cornu on one side or the other, between my catgut stitches, so that the uterine cavity was connected with the peritoneal cavity where the missing ovary was located, and without the intervention of the tubes.

The case becomes especially instructive when considered in connection with the reported cases in which stumps of tubes, which had been tied off by means of mass ligatures at previous operation months or years before, were found to have patent canals leading into the uterus; and also with those cases found in literature, of pregnancy following removal of both ovaries and tubes, assuming in the latter cases that a portion of ovary had been included in the ligature which was tied about the ovary and tube, or, less likely, the existence of a third ovary.

In my case every bit of tubal tissue was carefully removed and in spite of this fact ova from the lost ovary succeeded in getting into the uterus and becoming fertilized, illustrating the persistency with which Nature in the face of difficulties maintains a path for the passage of the ovum, and in marked contrast to our cases of resection of closed tubes in which, pregnancy not supervening, we must assume that the tubes subsequently became closed.

TROPACOCAINE HYDROCHLORATE.—A SUBSTITUTE FOR COCAINE HYDROCHLORATE IN SPINAL ANESTHESIA.

BY WILLY MEYER, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

In a recent communication (*Centralblatt für Chirurgie*, March 2, 1901), Dr. Karl Schwarz, Hospital Surgeon in Agram, publishes his experience with tropacocaine in spinal anesthesia. With the view to avoiding the annoying immediate and after-effects resulting from the use of the ordinary cocaine in this kind of anesthesia, Schwartz first experimented with eucaine B, but soon discarded it, since the same disagreeable symptoms connected with the use of cocaine were observed and the analgesic effect was much weaker.

He then tried to utilize the experience of R. Pitesci, who had found that a second subarachnoid cocaine injection on the same patient is not attended by any of the unpleasant effects generally seen at the first injection. Schwarz, therefore, proceeded to immunize the patients, so to speak, against the effect of the cocaine, by giving them a hypodermic of ⅓ grain of cocaine the day preceding the operation. However, the result was not satisfactory. As a third trial he employed tropacocaine. After a number of carefully conducted experiments he found that 5 centigrams (5/6 grain) of this drug, injected into the subarachnoid space, produced as perfect an analgesia as the ordinary cocaine, and none of the usual symptoms, such as pallor, perspiration, nausea, vomiting, headache, dizziness or rise of temperature were observed in any of the sixteen patients thus rendered partially analgesic by him. Ten minutes after the injection analgesia was generally complete and absolute until the end of the operation, the latter having lasted as long as two hours in one instance.

Two days after the respective number of the *Centralblatt* had come into my hands, it so happened that I had to perform nephrectomy for tuberculous disease in a patient, thirty-seven years of age, who had been afflicted with urinary symptoms for more than three years. He was much emaciated, expectorated a scanty amount of sputum containing tubercle bacilli, had hectic fever and such continuous pain in his left side that he was unable to walk straight, and was deprived, more or less, of sound sleep. Within the last six months the pain had extended to the right side. Urinary analysis showed that in 2,040 c.c. of urine voided in twenty-four hours, he discharged only 13.6 grams of urea, thus proving beyond a

doubt that both kidneys were affected. Under ordinary conditions I should certainly have refrained from operating on a patient like this, and rather have sent him South, placing him under general hygienic régimé, etc. As it was, the incessant pain was becoming unbearable to the patient, and operation on the left kidney was clearly indicated. Naturally, I did not like to employ general anesthesia in a case like this, and so resolved to try tropacocaine. Knowing from correspondence with Dr. Dudley Tait, of San Francisco, who, as is well known, has made many interesting experiments with spinal anesthesia, that a larger quantity of liquid injected into the subarachnoid space would spread analgesia further upward, I dissolved 5 centigrams of tropacocaine in 50 minims of sterilized water immediately before operation, and injected the same between the fourth and fifth lumbar vertebræ, with the patient in the scorcher position. Twelve minutes later, the field of operation having been cleansed and the patient placed in the proper position, operation was begun. In addition a suggestive general anesthesia with one part of alcohol and two parts of water on Esmarch's mask was employed, a deception which I generally practise in cases of spinal anesthesia and which I can highly recommend, especially when dealing with neurotic patients. Simon's longitudinal incision was employed, the twelfth rib resected with Gigli's saw and the kidney brought in front of the wound. At this stage of the operation only did the patient complain of any pain; evidently the analgesia did not reach the upper pole of the kidney, so that the manipulations of loosening it from below the diaphragm, as well as traction on this part of the organ, were felt by the patient. The ureter was then tied and, after proper isolation, the vessels were ligatured *en masse*. An anomalous plexus of vessels entered the lower pole of the kidney.

The operation was an almost bloodless one, the patient certainly having lost not more than a tablespoonful of blood. In view of the fact that the urine was loaded with tubercle bacilli and that some urine had entered the wound when dividing the ureter and, later, cauterizing and ligating its stump, the deep wound was drained in part and the upper angles were closed with catgut stitches. The operation lasted about forty-five minutes.

During all this time the patient had not complained of pain, except on traction of the upper pole of the kidney. There had not been any nausea, vomiting, perspiration nor pallor. The pulse, which had been 100 before operation, had gone up to 130 and 140 at times, but was full and regular throughout the operation; a hypodermic of 1-50 of nitroglycerin had a markedly beneficial effect upon its character. Half an hour after the injection, analgesia was still perfect up to a line corresponding to the junction of lower and middle third of the space between the umbilicus and zyphoid process. After completion of the operation, the patient smiled at the narcotizer, telling him that he (the patient) had fooled him in making believe that he was sleeping, when in reality he had been wide awake the entire time—certainly a significant joke, when *we* had tried to fool him. Following the operation none of the usual complications seen after the use of cocaine hydrochlorate were observed. There was not any rise of temperature, vomiting, headache nor other neuralgia. The patient felt perfectly well.

The removed kidney showed a beginning tuberculous abscess in the upper pole of the pelvis and numerous tuberculous infiltrations of the parenchyma up to the cortex. Very little urine, loaded with pus, was passed during the first twenty-four hours following the operation, still less during the next day. On the close of the second day urinary discharge ceased altogether. Evidently the ureter had become clogged, and an operation upon the other kidney was therefore decided upon. This was again done under spinal anesthesia seventy-two hours after the first. This time the patient was rather nervous, and begged to be rendered unconscious. However, after explaining to him the risks involved in general anesthesia, he agreed that I should proceed in the same manner as before. Again 5 centigrams—this time dissolved in but 40 minims of sterilized water—were injected. On beginning to operate, ten minutes later, the patient complained of pain. Ten minutes later, anesthesia yet seemed to be somewhat imperfect; handling of the kidney, especially traction on the same, was again painful. Resection of the twelfth rib, which again was necessary, however, passed unnoticed. The right kidney was very large, and, to my dismay, in a state of cystic degeneration and filled with pus. The cysts were evacuated. The kidney was then replaced and the wound drained. During the entire operation the pulse did not vary in frequency, was of good quality and did not require any stimulation: and again, none of the so often seen symptoms following injections of the ordinary cocaine were observed, neither during nor after the operation.

Certainly, this second anesthesia was not as ideal as the first. The cause may be due to altered circumstances; the general condition and nervous apprehension of the patient and the fact that the salt had been dissolved in ten minims less than at the first anesthesia.

Two days after this operation I had a third experience with tropacocaine which, exciting as it was, proved beyond a doubt the superiority of tropacocaine over cocaine, as regards avoiding the subsequent clinical complicating features.

Mr. J. S. had had nephrotomy performed eight years ago for right renal suppuration. About two ounces of pus had been removed from the pelvis and the latter drained. No stone was found. During convalescence the left kidney became seriously affected: marked renal hematuria and pyuria. Patient improved under symptomatic treatment. Repeated attacks of pain in the left lumbar region pointed to a continuation of the disease on the left side. Catheterization of the ureters done by me in 1897 pointed to a sup-

purative process in the left kidney, for which nephrotomy was proposed. The patient refused operation and did not consult me again until the beginning of March, 1901, by which time the frequent pains in the left kidney had become unbearable.

Cystoscopy showed that the mouth of the left ureter was blocked by a calculus which also could be felt later with the stone-searcher. Urinary analysis which had been made two days previous, therefore referred to the excretion of the right kidney only, and proved beyond a doubt that the same was still diseased. Under stimulating treatment the obstruction in the left ureter was removed; an immense amount of coagulated fibrin, pus and small irregular pieces of calculus were passed. After this the patient rapidly recuperated, but the pain in the left side persisted, though less severe. Analysis of the material passed after the blockade of the left ureter had been raised made it probable that a phosphatic shell had been loosened by the suppurative process from a more compact nucleus. An X-ray picture was taken, but failed to show anything definite. Exploratory nephrotomy was proposed, accepted and done under spinal anesthesia with tropacocaine on March 23d. Puncture between fourth and fifth lumbar vertebræ, with patient in scorcher position. The needle had to be introduced deep. While injecting the first two-thirds of the solution (5 centigrams dissolved in 50 minims of distilled water), it was noticed that the syringe worked rather hard. After pushing the needle forward for about two millimeters, the remainder was emptied with the usual ease. Conclusion: tip of needle must have been accidentally withdrawn for a minimal distance, but sufficiently to cause the first portion of the syringe to be injected probably outside of the dural sac. Fifteen minutes later, anesthesia had not yet begun; second injection was therefore made at same spot. Needle struck subarachnoid space about one inch nearer than before. This time 4 centigrams were injected and certainly all emptied into the subarachnoid space. Complete anesthesia was established two minutes later.

Fifteen minutes after completion of second injection, there was sudden acceleration of pulse, which soon became very thready and disappeared entirely at radials. Profuse perspiration; patient in complete collapse; nausea, vomiting. By placing him in pronounced Trendelenburg posture and employing strong hypodermic stimulation with nitroglycerine, hyoscine hydrobromate, etc., the heart's action soon improved and allowed us to finsh the operation. Complete anesthesia lasted for one hour and fifteen minutes; then began to wear off. Manipulation of the kidney was again rather painful.

Of the first injection, 0.016 of a gram, approximately, had entered the suarachnoid space, 0.034 the tissues outside of the dura mater sac. At all events, the patient had gotten 0.09 of a gram (1½ grain) of tropococaine into his system, a dose almost twice as large as that usually required. I fully admit that the amount injected was too large. On the other hand, it is a most difficult question for the surgeon to decide how large the dose should be for a second injection if such be required. In another similar emergency, I should certainly administer a hypodermic of 1-50 to 1-25 of nitroglycerine *before* giving the second spinal injection, and place the patient in Trendelenburg's posture as soon as the needle has been withdrawn. I believe that by so doing annoying experiences like the one just related may be averted.

It certainly would be distressing to be forced to make a third injection if the second should prove to have been insufficient, and the surgeon in his endeavor to guard against such result is apt to inject more than is absolutely necessary. Of course, this latter point can never be definitely determined beforehand. But, be this as it may, the case proves beyond a doubt to my mind the absolute superiority of tropacocaine over cocaine in spinal anesthesia. The patient did not suffer any of the numerous symptoms incidental to the use of cocaine in spinal anesthesia. He developed no temperature, felt perfectly well during the latter part of the afternoon and night following the operation. At the beginning of the third twenty-four hours after the operation the temperature once touched 102° F., with a pulse of 72. This rise may have been due to the wound. After the gauze tampons, partially filling the wound only, had been removed the temperature promptly dropped to normal.

On March 28, 1900, I removed a multiple papilloma of the bladder in a man aged forty-nine years, under spinal anesthesia with tropacocaine. A few drops of the 50 minims of distilled water in which the five centigrams of the salt had been dissolved, were lost. Patient got between 0.04-0.045 tropacocaine into his subarachnoid space. During the first forty-five minutes of the operation, which was begun ten minutes after completion of the injection, analgesia was perfect. Then the patient began to complain. He felt the working of the Paquelin cautery during the shelling out of the pedicle of the second tumor. The operation was finished under general anesthesia.

It seems that fully 5 centigrams (⅝ of a grain) are required to produce satisfactory analgesia for an operation lasting one hour and longer. perhaps 0.06 (1 grain) of the salt may be injected with impunity previous to more serious operations, if a subcutaneous injection of 1-50 of nitroglycerine is given at the same time. More study is required. It will most probably be shown that certain individuals have an idiosyncrasy also with regard to tropacocaine. My second case, just reported, certainly points that way.

Tropacocaine was discovered by Giesel in 1891 in Javanese coca leaves, and more closely studied by Liebermann, who succeeded in producing it synthetically. Later Willstatter discovered a way of preparing tropacocaine from tropine a fractionation product of atropine and hyoscyamine.

His method is the one now exclusively employed in the manufacture of the alkaloid. Since then the salt has been studied by many investigators, and the following points of importance in comparison to cocaine were found:

1. Tropacocaine is less than half as toxic as cocaine.

2. The depressing action, both on the cardiac motor ganglia and on the cardiac muscle, particularly the latter, is much greater with cocaine.

3. Recovery from its effects is much more rapid.

4. The solution is by far more stable than that of cocaine hydrochlorate.[1]

It would therefore seem that the surgeon is allowed to have prepared and preserve a solution for spinal anesthesia. It also seems that we may be allowed to sterilize it by boiling. However, this latter point will have to be determined by actual experience.

I shall hereafter have the solution made as follows:

Tropacocaine hydrochlorate	gm. 0.015 (¼ gr.)
Sodium chloride.....	0.06 (1 gr.)
Distilled water.....	10.0 (5iiss.)

Each ten minims of this solution contain one centigram (⅙ grain of the salt) fifty minims, therefore, contain 0.05, the generally required dose.

In view of the importance and great interest that is attached to the subject of spinal anesthesia at the present time, I thought I would publish my experience thus far, even if only to add a few more instances, demonstrating the usefulness and superiority of tropacocaine in spinal anesthesia, to the sixteen cases which have been reported by Schwarz.

I have thus far employed spinal anesthesia in the surgery of the urinary system only such as Bottini's operation, litholapaxy, vesical tumor, primary and recurrent, and must confess that in every instance I have been delighted with its immediate local analgesic effect. And, while, of course, the unpleasant symptoms accompanying the use of cocaine in spinal anesthesia are deplorable, it must be remembered that general anesthesia also quite frequently is attended by the same annoying symptoms, except, perhaps the fever. I have been satisfied so thoroughly with my results that I fully made up my mind to continue spinal anesthesia in urinary surgery. Now, however, since the drawbacks hitherto connected with this mode of producing widespread analgesia seem to have been removed, I shall be all the more ready to make use of this kind of anesthesia whenever the indication is present, and, I am sure, others will feel the same way in regard to this question.

Of course, further investigation and careful observation are needed to settle definitely many important and interesting points which are still *sub judice*.

A STUDY OF CASES PRESENTING SYMPTOMS OF ASTHENOPIA AND ANOMALIES OF THE OCULAR MUSCLES IN WHICH ABLATION OF THE MIDDLE TURBINAL WAS EFFECTIVE TREATMENT.

BY HEBER NELSON HOOPLE, A.B., M.D.,
OF NEW YORK CITY, BOROUGH OF BROOKLYN;
SURGEON, EYE DEPARTMENT, WILLIAMSBURG HOSPITAL; CLINICAL ASSISTANT, NEW YORK EYE AND EAR INFIRMARY.

The late Dr. Henry D. Noyes has said[1] of the class of cases to which the following histories belong, "The judicious and skilful treatment of cases of muscular asthenopia with all the complications which may co-exist is the highest problem in ophthalmology." He has also stated,[2] "asthenopia as a reflex effect from the nasal mucous membrane. . . . was noted by Dr. Schweigger. I have long recognized an intimate relation between nasal catarrh and chronic conjunctivitis, and that with it asthenopic symptoms are frequent." These words of that careful, scientific investigator of all knowledge in the field of ophthalmology, have been ever present to the writer when studying his cases and he seeks here only to add his quota of observations to the total sum of them that shall ultimately clarify these problems. In doing so he asks acceptance of his facts alone and not of his theories or inductions except so far as they spring logically and necessarily from the facts. The aim to find important truth, and not the interest inherent in the histories, is the sole reason for their presentation.

Case I.—Miss M. K., seamstress, twenty-seven years old, robust, muscular and in good general health, complained to me on December 2, 1899, that for years her eyes had been "weak." For more than two years her vision had been much poorer than before, blurring in her work on white goods. She had constant daily headaches and was becoming irritable. Occasionally her headaches were severe causing a dull, heavy, pressing ache, chiefly in the left temple, extending to both the vertex and occiput. They were accompanied by throbbing at the left side of the nose and inner canthus of the left eye. Vision $^{2}/_{10}$ with each eye. Considerable astigmatism; at 20 feet, adduction 17°, abduction 6°, esophoria 1°. At 10 inches, exophoria 5°, on dissociation with 10° prism.

December 5, 1899. Under atropine V = $^{1}/_{10}$, O. U. The following correction was given which raised V to $^{4}/_{10}$ in each eye. O. D. + 1.00 D ⌣ 4.00 cyl. ax. 10°: O. S. + 1.25 D ⌣ —5.50 cyl. ax. 180°. These glasses made considerable improvement. Vision was clear. Patient could work with comfort, she became less irritable and was confident she was all right.

July 7, 1900, nearly seven months later, she returned and said that something must be going wrong. Her glasses no longer relieved

[1] "Diseases of the Eye," 1896, p. 207.
[2] Ibid., p. 197.

her headaches though she saw clearly with them. Nervousness and sleeplessness were reappearing. Eyes were bloodshot and swollen mornings. Former pressure-pains on left side of head going to vertex and occiput were now more severe accompanied at times by the feeling of "cold water trickling down" the left temple as well as throbbing at the inner canthus of the left eye and numbness over it. Seven weeks ago burst into tears at her work in one of these attacks of headache. She feared she might go crazy with it. Re-examination of her eyes satisfied me that her glasses were not at fault. The muscle tests showed the same findings as before. In making my first examination in 1899, I had not omitted to make my routine examination of the nose; but I had not noted any fault, probably because impressed with the considerable error of refraction to which for the moment all blame was attached. I now examined with more care and found the septum somewhat deflected opposite to and against the left middle turbinate. The right turbinates were hypertrophied, the middle being overgrown into the deflection and touching the septum. The left middle turbinate was tightly compressed and exquisitely tender. July 10, 1900. From my experience with similar cases I knew that removal of the left turbinal was demanded and consequently removed it. July 11, 1900. The severe head-pain is gone. Some shooting pains on right side of the head and tinnitus in the right ear. Some tinnitus of a blowing character had occasionally been felt for a long time in the left ear but not before in the right.

July 25, 1900. For more than a week, the patient has been free from all her symptoms, her new sense of comfort being so marked that she "feels like a new person" and indulges in extravagant expressions of delight.

October 23, 1900. Three months have elapsed since the last record. No headaches, no discomfort during the period. Patient sews all day without discomfort. There are no nervous spells, irritability, nor fear of going crazy. The muscle tests show little change. Adduction 15°, abduction 6½°. But, whereas there was at the near-point a slight exophoria of 5°, now there is equilibrium.

February 8, 1901. Comfortable use of the eyes has continued to the present time. All severe symptoms are a thing of the past. The patient is contented and satisfied that now she is all right, having enjoyed six months of freedom from the former symptoms and terrors. It is noteworthy that the nervousness and irritability which characterized her former state have disappeared. Besides, the tinnitus of the left ear which had been obtrusive enough at times to be greatly disturbing, has been gradually diminishing.

Case II.—E. A., girl of nineteen years of age, in good health, sensible and without unusual nervous susceptibilities, decidedly not neurasthenic. Two years ago had "grip." Following that had colds in the head almost constantly, even during the summer of 1899, as well as during the winter of 1899-1900. She had occasional twinges of rheumatism in the right shoulder in winter. During this period the eye-lids felt heavy and smarted, the eyeballs pained and the forehead ached, especially over the right eye. She would often awake at night with pain referred to the right ear. Use of the eyes in reading caused headaches, so that she gave up reading. In July, 1900, she consulted the best oculist known to her, an eminent man of cosmopolitan reputation, a member of the American Ophthalmological Society, who examined her eyes with great care first without a mydriatic, afterwards with a mydriatic. He prescribed for her as follows: O. D. + .25 D. cyl. ax. 180°; O. S. + .25 D. cyl. ax. 90°. Recognizing muscular imbalance, he advised her to have prism exercises which she was at that time unable to take. These glasses were worn with some benefit, but they did not give her enough benefit to enable her to read without headaches.

When I first examined her, October 11, 1900, I found her vision O. D. = $^{10}/_{10}$, O. S. = $^{9}/_{10}$. Very slight astigmatism at 90°, for which her glasses seemed a full correction. Media clear, fundus normal. Adduction 12°, abduction 6½°, exophoria 1°. At the near-point, exophoria 12°. No improvement on exercise of muscles. November 17, 1900. At near-point, exophoria 10°. At 20′, adduction 15°, abduction 6°, equilibrium, no hyperphoria. Still has same discomfort on use of the eyes. Both middle turbinals are tangent to the septum, but the right is pressed tightly against it. She gave the history of a fall upon the ice some years before in which the nose received a severe impact and bled profusely. There was just enough deflection of the septum against the right middle turbinal to lay that fall under suspicion as the cause of it. At this time it is impossible to carry adduction beyond 15°. Removed the right middle turbinal.

November 25, 1900. At near-point, exophoria 9°. At 20′, adduction 25°, abduction 7°, esophoria 6°. November 27, 1900. At near-point exophoria 8°. Adduction 29°. December 2, 1900. Patient reads an hour at a time without discomfort, after which she perceives tire on further use of the eyes. At near-point an initial exophoria of 2° gradually passes to 4°, 6° and even 8°. But, on exercise with prisms to run up adduction to its limit, exophoria at the near-point disappears and an initial esophoria of 2° passes slowly to 4° where it is maintained during the examination. December 6, 1900. The same behavior of muscles for near and on exercise with prisms. At 20 feet, equilibrium, esophoria 2° and 3° are obtained by various tests.

Tests were made every few days and prism

exercises given until December 16th, when at the near-point there was initial equilibrium passing slowly into exophoria 1° slowly ascending to 8°. After prism exercise in which adduction reached 55° the near test showed at first equilibrium rapidly leaping up to esophoria 24° and then slowly subsiding to esophoria 10° which is maintained during the examination. Reads with comfort. The patient has not since been examined; but on January 1, 1901, she writes that she can read all evening without the least discomfort, keeping this up from day to day without wearing her glasses.

Case III.—Miss A. B., twenty-two years of age, bookkeeper, mentally well-poised, not especially nervous, complained on May 1, 1900, of having had severe headaches for some years which were becoming more frequent and more severe, until of late they occurred almost daily and were "terrible." O. U. V = $^{9}/_{10}$. Javal O. U., .50 cyl. ax. 90° *with the rule*. Accepts + .50 S = $^{10}/_{10}$. Adduction 33°. Abduction 6½°. Esophoria with Maddox rod 18°, prism 16°, cobalt 12°, Graefe 12°. At the near-point, esophoria 2°. There being good muscular balance for function at the near-point, cause was sought elsewhere for the severe symptoms. A menorrhagia of moderate amount two years ago had yielded kindly to treatment by her physician and was no longer in evidence. As in the other cases, however, a faulty condition of the right middle turbinate was found. The left middle turbinate was normal. The right was removed. Three weeks later, on May 23, 1900, adduction was 25°, abduction 6½°, esophoria 10° (with four tests). At the near-point esophoria was 7° During these three weeks there was not once a severe headache, but there were some light headaches becoming lighter and fewer. June 25, 1900. Improvement maintained. October 19, 1900. No severe headache at any time since the operation. Comes to me at this time for some blurring of vision which has been with her during this whole period. Under homatropine V. O. D. = $^{2}/_{10}$ +. Javal .50 c. a. 85° + 1.00 s ⌒ + .25 cy. ax. 85° = $^{9}/_{10}$ +. V. O. S. = $^{3}/_{10}$ +. Javal .50 c. a. 90°. + .75 S ⌒ + .25 cy. ax. 90° = $^{9}/_{10}$.

Ordered

$$\begin{cases} \text{O. D.} + .50\ \text{S} \frown + .25\ \text{cy. ax. } 85° \\ \text{O. S.} + .50\ \text{S} \frown + .25\ \text{cy. ax. } 90° \end{cases}$$

After wearing this correction two weeks, the patient reported freedom from blurring as well as from headaches.

February 12, 1901. Nine months without severe headache. Menstruation quieter and better since than before operation. At near-point esophoria 2° to 4°. Abduction 5°, adduction 37°, after which esophoria at 10″ ran up to 18° and steadied itself at 14°. At 20 feet, esophoria 10°.

Case IV.—C. B. C., a young man twenty-two years old, matter-of-fact, steady, unemotional, of good habits, came to me December 21, 1899, for examination of the eyes. He complained of headaches referred to the forehead over the left eye, pain in both eyes and in the eye-lids when at his work on books during the day and utter inability to read at night without great discomfort. For four years he had been wearing + .50 d. s., O. U., given him by an optician, without getting any abatement of his symptoms. I found his vision $^{10}/_{10}$ with each eye, astigmatism one-half diopter *with the rule*, adduction 17°, abduction 7°, exophoria ½°. At near-point, equilibrium. Under a mydriatic V = $^{8}/_{10}$. With — .50 S, V = $^{10}/_{10}$. Clearly this error did not cause his symptoms. Found a spur on the left side of the septum digging into the inferior turbinate in a very narrow nasal cavity, also the left middle turbinate tightly compressed against the septum. Nothing was done with the nose then. The patient made occasional visits to the office for prism exercises. Equilibrium at the near-point was not found subsequent to the first examination. Nothwithstanding these exercises for 6 months, adduction became weaker and exophoria at the near-point greater, until on June 4, 1901, adduction was 10°, abduction 6° and exophoria 10° (at the near-point). Removed the spur from the septum.

July 13, six weeks later, the patient still has headaches on use of the eyes; adduction 17°, abduction 6°, exophoria, 2°. At the near-point exophoria 10°. Removed the left middle turbinate. July 17, 1900. No headache since the operation though the eyes have been in constant use. Exophoria at the near-point 7°, adduction 22°, abduction 6½°. July 25, 1900. Patient says he can now read any length of time without discomfort.

October 19, 1900. Patient has frequently had discomfort in use of his eyes since the last visit but more especially the last few weeks. Found synechial bands between the septum and the outer wall of the narrow nasal space. Severed these bands and introduced thin splint to prevent further adhesions. December 6, 1900. The means adopted were effectual. The nares remained freely open. The patient meanwhile had comfortable use of the eyes. At the near-point exophoria 4°, slowly advancing to 6°. Exercise with prisms carries adduction up to 29°, after which test at the near-point shows esophoria 4° to 10° slowly returning to 4° and remaining there during the examination. At 20 feet, all tests show exophoria ½°. The patient can read for three hours at night without discomfort. December 27, 1900. Practically the same findings and the same satisfactory report as three weeks ago.

January 15, 1901. Improvement in all particulars. Equilibrium at the near-point slowly passing into exophoria as high as 6°. Then prism exercise raises adduction to 32°, after which there is esophoria 4° at the near-point,

steadily maintained. The patient regards himself as cured of his trouble.

These few cases are selected as some of the types of many others under observation.

In Case I. the refraction was very faulty and seemed to be the adequate cause of the symptoms until complete and careful correction worn for six months failed to ensure relief though it gave fairly good and clear vision. But relief immediately followed removal of pressure between the middle turbinate and the septum. That relief has been complete and permanent and is accompanied incidentally by disappearance of a slight exophoria of 5° for the near-point at which there is now equilibrium and perfect comfort in constant use of the eyes.

In Case II. there was almost no error of refraction but there was decided exophoria at the near-point. Use of the eyes thereat gave headaches too severe to permit of use of the eyes in reading. The history of injury, the finding of pressure, the removal of this pressure, the restoration of comfort in use of the eyes at the near-point because of slow but sure recovery of force and sustained innervation of muscles as evidenced by the change from utter inability to exceed 15° of adduction before operation to ability to reach 55°, and finally the assertion of strength and control by these muscles in the exercise of their function at the near-point increasing on daily use of the prisms until now constant use of the eyes thereat is not only tolerated but enjoyed, these all constitute a congeries of facts and relations that give importance to the one new factor, ablation of the middle turbinal.

The error of refraction in Case III. evidently had nothing to do with the disturbing headaches, for these headaches were removed at once on removal of the offending middle turbinal when as yet no correction had been given for the error of refraction.

Yet during this period of exemption from headaches there was some blurring of vision until the correction was given. Meanwhile very little change took place in the behavior of the muscles: their strength was constant, their harmony of innervation was somewhat bettered. Esophoria for distance was lessened, that for near increased, a relation of adjustment occurring in such cases found associated with more comfortable use and both instantly falling to a minimum when the correction is worn. This betterment followed removal of pressure from the terminal filaments of the nasal branch of the ophthalmic.

In Case IV. only when the left naris was put right and maintained so, did the muscles manifest strength in adduction and good behavior at the near-point, their innervation for that function having again become responsive to efficient use. Hence there can be no question of asthenopia from error of refraction. Neither can there be an iota of question of a neurotic constitution. It seems to be purely a matter of disturbance of innervation of the ocular muscles by irritation of a particular area of nerve distribution in the nasal mucosa.

That a larger proportion of cases of anomalies of the ocular muscles is dependent on this form of disturbance than has generally been suspected, is more than probable.

I wish here to draw attention to a paper in the *Medical Record*, January 30, 1885, by Dr. E. Gruening in which that careful and experienced observer of scientific phenomena gives the history of a series of cases in which treatment of the nose alone was effectual for the cure of the eye troubles although no symptoms were referred to the nose and treatment directed to the eyes had been in vain. He then employs this argument: If an irritant to the nose can cause lacrimation and other eye symptoms, then *a priori* a continuance of such irritation may keep up the disturbances; and, if treatment directed to the eyes fails to relieve them but treatment of the nose does, the more positive *a posteriori* argument presents itself—*causa sublata, tollitur effectus.*

ACUTE TRAUMATIC MALIGNANCY.[1]

BY WILLIAM B. COLEY, M.D.,
OF NEW YORK.

In a paper entitled the Influence of Injury upon the Development of Sarcoma, read before the New York Surgical Society, November 24, 1897, I called attention to the fact that a very large proportion of patients with sarcoma gave a history of antecedent injury, and I endeavored to show that such trauma had an important etiologic relationship to the tumor. A further and more careful clinical study of malignant tumors has confirmed my conviction that injury constitutes a much more important factor in the causation of malignant tumors, both sarcoma and carcinoma, than has been generally recognized. My earlier paper was based upon an analysis of 170 personal cases of sarcoma, of which number 46 cases or 27 per cent. gave a distinct history of trauma. Of these cases, *classified anatomically*, 18 were osteosarcoma, including 3 osteochondrosarcoma: 6 sarcoma of the soft parts. According to *pathological classification*, there were 29 cases of round-celled: 5 spindle-celled; 5 melanotic: 2 chondrosarcoma; 1 cylindroma; 3 mixed-celled sarcoma and 2 doubtful.

At my request, Dr. C. J. Kane, late house-surgeon of the General Memorial Hospital, very kindly made an analysis of one hundred cases of sarcoma treated at the General Memorial Hospital within the last three years with the object of determining the relative frequency of antecedent trauma. His statistics give a larger proportion of cases due to in-

[1] Read before the Medical Society of the Greater City of New York, Nov. 12, 1900.

jury than was noted in my own cases. In 63 local injury of some form had been received prior to the development of the tumor; 27 other cases gave a history of chronic irritation and in only 10 cases was there a history of neither trauma nor irritation.

Of these 100 cases, 17 were small round-celled, 3 large round-celled, 25 spindle-celled, 6 melanotic, 7 chondrosarcoma, 16 osteosarcoma, 5 myelosarcoma, 2 angiosarcoma, 2 adeno-sarcoma, 4 fibrosarcoma, 3 mixed-celled, 3 myxosarcoma, 5 lymphosarcoma and 2 only in which the diagnosis was not confirmed by microscopical examination.

In 68 out of this series of cases the sarcoma occurred in the soft parts; in 32 in the bone.

The tumor was noticed to appear immediately after injury in 6 instances; in 16 cases it was first noticed from one to three months later; in 21 within three to six months; in 24 within six to twelve months; in 1, fourteen months; 1, seventeen months; 1, two years and 1, four years after injury.

Since the publication of my first series have observed 100 additional cases of sarcoma. The histories of these have been studied with much care, especially with regard to the question of antecedent injury. Forty patients gave a distinct history of injury prior to the appearance of the tumor and 8 others, a history of local irritation of some form. In 13 of these 40 the tumor developed within one month after the receipt of the injury, and in 8 of 13 cases within one week.

Adding these to the 18 in my previously reported list, occurring within one month after the trauma (8 within one week) we have a total of 31 cases that may be properly classed as examples of acute traumatic malignancy. Thus, of my entire series of 270 cases of sarcoma, 86 or 31.8 per cent. have a distinct history of antecedent trauma; while in 31 or 11.5 per cent. the tumor developed almost immediately after the injury. There is no special reason for separating these 31 so-called acute cases from the others, save for the fact that in these the connection between the injury and the development of the tumor is so clear and unmistakable that it cannot be lightly explained away as is too often attempted in the cases in which longer intervals of time have elapsed, on the theory of a poor memory or a vivid imagination on the part of the patient. If we can establish an etiological relationship between the trauma and the development of the sarcoma in the group of acute cases, the same relationship will probably be found to exist in the cases of slower development. The more I study the clinical aspects of malignant disease, the more firmly am I convinced that independent and oft repeated statements of intelligent patients with reference to any point, be it concerning heredity, diagnosis or trauma, are worthy of far more consideration than is usually accorded them by the medical profession, and certain it is that the old opinion of the laity, that malignant tumors are frequently caused by blows and injuries, receives more and more support the more familiar we become with the actual facts. It is more than probable that, instead of overestimating the percentage of cases with antecedent trauma, we greatly underestimate it, for the reason that in many cases, especially those in which the tumors are of slow development, the patient has quite forgotten the injury.

The histories of the acute cases show that a very slight injury may be sufficient to produce the growth, and such an injury would probably have been forgotten, had the tumor not developed for months or years after. As recently as 1882, Harrison Cripps of London, although a believer in trauma as a causative factor in sarcoma, stated that not more than 7 or 8 per cent. gave a history of injury. This statement, I think, rested not so much upon facts as upon imperfect histories and upon small series of cases.

Löwenthal, who collected 316 cases of sarcoma in medical literature, giving a previous history of local injury, found that of 190 cases in which the interval between the receipt of the injury and the appearance of the tumor was definitely stated, the sarcoma was observed within one month of the injury in 135. The statistics of Wolff show that 20 out of 100, or 20 per cent., give a history of trauma; while in a series of 344 cases of carcinoma, of the same author, trauma was observed 42 times, or in 12.2 per cent. Samuel Gross, who collected reports of 165 cases of sarcoma of the long bones, found that more than 50 per cent. show a history of trauma.

As evidence that greater attention is given to trauma at the present time may be cited the recent paper of McWilliams (MEDICAL NEWS, April, 1900) giving statistics of 100 cases of carcinoma operated upon at the Presbyterian Hospital of New York, within the last ten years. This series shows a history of antecedent trauma in 44.6 per cent. of the cases.

As regards the influence of trauma upon the development of malignant tumors, Sir William Mitchell Banks, in his recent and very valuable lectures on Cancer of the Breast, states that he has never been able to make out that milk abscesses or scars of incisions have been the starting-points of cancer, and that he has no recollection of a patient directly attributing cancerous growths to them. On the other hand, he says that he has very often heard most clear and circumstantial histories narrated in which blows were asserted to have been the primal cause of the trouble. The argument that men are more liable to blows on the breast than women, he disputes, stating that women are always in the way of getting knocks from young children or from

articles of furniture, such as cribs, beds, etc., among which they are constantly working. Besides, the breast of a woman being so much larger and more prominent, it is much more exposed to injury than that of man. He states that he has "received very succinct accounts from intelligent women of blows from pieces of furniture or kicks from young children in which there was pain immediately afterward, sufficient to place the exact spot in the breast. Then the pain has gone away, they have almost forgotten the circumstance until some day a lump is found in the old site of injury." Banks believes that, if it were true, as has so often been stated, a woman's attention is directed to the tumor which is already lying concealed in her breast, she would discover it at once on receipt of the injury. The theory that the patients invent the story of previous injury, after finding a lump, he believes, is inconsistent with the high degree of intelligence of many of his patients. Roger Williams says that "in examining the histories of 137 women with cancer of the breast, 1 out of every 4 made a statement of previous trauma. In conclusion Banks says that "after the way in which the vulgar, but rooted belief in the infectiousness of phthisis of the Italian peasant has, in the light of modern discovery, triumphed over the contemptuous disbelief of the whole world of medicine, I am not disposed to abandon all belief in statements of women whom we will even admit to be anxious to find a cause for their malady. Constant repetition from different sources strengthens even a weak tale, provided the evidence be steadily in the same direction. I have investigated these stories too often not to feel that, stripped of all exaggeration, there is a distinct element of truth in them. Remember, I do not make any attempt to assert that cancers of traumatic origin are at all frequent, but I believe in the possibility, and, indeed, in the strong probability of their occurrence."

With reference to the influence of trauma upon tuberculous joint disease Banks states, "I am not one of those who look for a mechanical cause of cancer in virtually every case, but I venture to say that there is no practising surgeon in this country, who has much to do with joint disease, who does not recognize the immense importance of wrenches, blows and sprains in the production of early inflammatory changes in and about joints, which ultimately end in what is known as articular tuberculous disease. I was educated in exactly the opposite view, namely, that the tales which the mothers told about injuries to their children's joints were all nonsense, but I was forced out of this belief by the irresistible arguments of experience." He further adds that "one feels the more inclined to this view from the knowledge that acute traumatic malignancy is a well-recognized disease. Scattered throughout the medical journals are so many cases of its occurrence that no possible doubt can be entertained about its existence."

Sufficient evidence has been presented, I think, to prove the existence of definite histories of antecedent trauma in a large proportion of cases of malignant disease. It remains for us now to briefly consider whether or not there is any etiological connection between the injury and the development of the tumor. Numerous conjectures have been made in efforts to explain these facts. The theory of so-called constitutional diathesis has perhaps had the largest number of supporters, among whom may be mentioned Butlin, Barwell and many of the German surgeons. Butlin believes that the injury would be harmless unless occurring in a person having this constitutional diathesis. The theory of a local predisposition, which may be either inherited or acquired, is held by Virchow who claims that mechanical irritation or injury produces a specific disposition of the tissues for tumor development. Krönlein regards traumatism as of little significance, believing that the local predisposition is due to a defective embryonal development. Lowenthal whose careful study of 316 cases of sarcoma with a history of previous local injury makes his opinion worthy of consideration, believes that there is sufficient ground for assuming that external irritation or trauma may give rise to the development of a tumor and, therefore, that traumatism may be considered as a direct etiological factor in the development of malignant disease.

My own opinion as regards this relationship has not changed since the publication of my former paper. As I then stated, I believe that the relationship between antecedent trauma and the development of sarcoma or carcinoma can be most rationally explained on the theory that such tumors are infectious, or of micro-parasitic origin. The analogy between sarcoma and diseases known to be of infectious origin is very striking. The clinical evidence, aside from the bacteriological or pathological, points more and more strongly toward a specific infection as the cause of sarcoma. The similarity between sarcoma and tuberculous disease is so pronounced, not only as regards clinical symptoms, but also pathological characteristics, that trained pathologists not infrequently are forced to admit that they are unable to differentiate between a tuberculous tumor and a round-celled sarcoma.

Granting for the moment that malignant tumors are due to an infectious micro-organism—and I may add, the evidence in support of this theory is rapidly increasing—the explanation of the relationship between trauma and sarcoma becomes at once clear and satisfactory. We have simply to follow up the analogy between sarcoma and other lesions known to be of infectious origin, for example, tuberculosis, osteomyelitis and periostitis.

We know that tuberculous inflammations of the bones not infrequently develop after an injury in children previously in good health. I have personally observed a number of such cases and so many have been reported, as Banks has pointed out, that there can be no doubt as to the etiological significance of injury in these cases. Any explanation that will apply to the causal relation between trauma and tuberculosis inflammation will apply to sarcoma. The most probable explanation would appear to be, that the micro-organisms exist latent in certain individuals, and under normal conditions they remain harmless indefinitely. The local trauma diminishes the vitality of the tissues and, hence, their resisting power, and the germs previously innocuous, gain a foothold and develop.

We know that it is possible to have suppurative periostitis from traumatism without any lesions or breaking of the continuity of the skin. The micro-organisms which caused suppuration must have been carried to the part by the blood, although the original starting-point of these micro-organisms we may not be able to locate accurately. The main conclusions to be drawn from the study of these cases are as follows:

1. Trauma is a very important factor in the causation of malignant tumors.

2. This relationship between injury and malignant tumors furnishes additional and by no means unimportant evidence in support of the infectious origin of such tumors.

The following cases are here reported as evidence bearing on the general thesis:

CASES OF ACUTE TRAUMATIC MALIGNANCY.

Case I.—Sarcoma of Femur.—T. B., forty-five years of age, male, blacksmith, without any hereditary history of cancer, was kicked by a horse on January 29, 1900, and sustained a small fracture of the lower end of the femur. The fracture was treated by the usual method of extension for a period of six weeks. As soon as the splints were removed, the patient noticed at the site of the fracture what he considered an abnormal enlargement, but the attending physician assured him that it was the usual callus which occurred during the repair of a fracture. This swelling, instead of diminishing in size, slowly increased and, finally, at the end of a few months became painful. About the middle of August, 1900, the bone at the site of the injury had increased so markedly in size that this, together with the increase in severity of the pain induced him to consult several other physicians. It was evident that a sarcoma had developed at the site of the injury. The patient saw me August 21, 1900, at which time physical examination showed the left femur to be two inches shorter than the right, and the patient was unable to walk without the aid of crutches. At the lower end of the femur there was a tumor about the size of a child's head, smooth in outline, firmly fixed and apparently originating in the bone. The joint was not involved. The skin over the tumor was freely movable and normal in character, although somewhat tense. The tumor itself was fairly firm in consistence.

The diagnosis of sarcoma of the femur being unmistakable, amputation at the hip-joint was

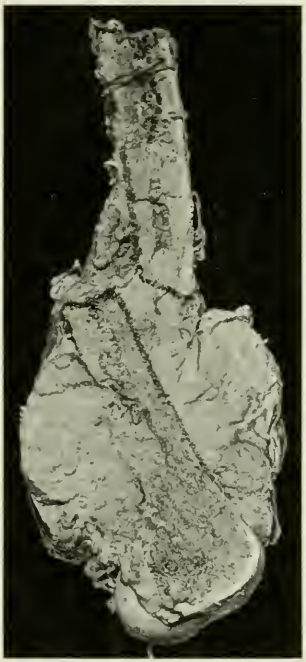
FIG. 1.

Case I.—Acute traumatic sarcoma of femur following fracture.

advised and performed by Wyeth's method, on August 29, 1900. Although the patient's general condition was not very good (he had a loud, well-marked systolic murmur). He made an uneventful recovery, the wound healing by primary union except at the site of the drainage-tube. The specimen of the tumor and the photographs which I present, prove conclusively that the tumor started at the exact site of the fracture. Several cases have been hitherto observed, and I have myself reported one, in which sarcoma developed at the site of an old fracture, but this is the first case with which I am familiar in which the tumor developed immediately after injury. In other words, this is a true example of acute traumatic malignancy.

Case II.—Round-Celled Sarcoma of the Testis.—M. M., aged twenty-eight years, driver by occupation, with good family history. Early in January, 1900, the patient fell astride a bar, injuring the right testis. A swelling appeared at once and never disappeared. About a week after the injury, the patient noticed that it was increasing in size. There was no pain at first, but later there developed a dull, dragging pain. Two weeks after the injury the patient went to an outdoor patient department in this city and was tapped for supposed hydrocele. Nothing but blood, however, was found. A second tapping, a few days later, gave the same result. On February 8th, or one month after the injury, I saw the patient for the first time. Physical examination showed a tumor of the right testicle, the size of an orange, soft and even semifluctuating in consistence, symmetrical in shape. There was little or no tenderness. The diagnosis of hematocele, with the possibility of sarcoma, was made and immediate operation advised. Two days later I operated and found about four ounces of dark, grumous blood in the tunica vaginalis, and the testis itself was enlarged about three times its natural size. Believing the disease to be malignant, I removed the testis together with the cord well up beyond the internal ring, the canal having been opened as in Bassini's operation for hernia. The first examination of the pathologist pronounced the disease non-malignant, but later a more careful examination of a large number of sections showed it to be round-celled sarcoma. There was at this time no evidence of the trouble in the abdomen. Two weeks after leaving the hospital, the patient was admitted to Dr. B. F. Curtis' service at the Bellevue Hospital, with a large abdominal tumor. Exploratory incision was made on March 16th, or five weeks after the date of the first operation. A tumor, the size of a man's head, was discovered in the region of the right kidney. A portion of the growth removed for microscopical examination proved to be round-celled sarcoma. The patient died April 18th of progressive cachexia.

Fig. 2.



Case I.—Acute traumatic sarcoma of femur.

This case is one of the most remarkable illustrations of acute traumatic malignancy that I have observed. The sarcoma developed immediately after the injury in an organ, up to that time perfectly normal, and ran such a rapid course that scarcely more than three months elapsed between the time of the injury and death of the patient.

Case III.—Sarcoma of the Ischium.—W. M., male, aged twenty-two years. In the winter of 1896, the patient fell upon the ice, striking severely upon the tuberosity of the ischium. The next morning he was not able to use his leg, and did not regain this power until three weeks later. A few days after the fall he noticed a lump at the site of the injury; it was hard and fixed to the pelvic bone, and continued to grow slowly in size until the time of my first observation, June, 1898, it had become a large inoperable, spindle-celled sarcoma.

Case IV.—Sarcoma of the Cheek.—D. L., female, aged forty years; good family history. In June, 1897, the patient received a blow from a fist on the left cheek. A swelling appeared at once and never disappeared, but gradually increased in size. It seemed to be situated between the skin and mucous membrane, just beyond the angle of the mouth. In about eight months it had reached half the size of a hen's egg and was removed. The disease recurred in a few months. A second operation was performed and, in November, 1898, a third, for recurrence. No microscopical examination of the growth made, but the frequent recurrences and clinical characteristics proved it to have been sarcoma.

Case V.—Small, Round-Celled Sarcoma of the Groin.—G. S., male, five and a half years old. In spring, 1899, the patient fell, injuring the right groin. A few days later a swelling was noticed in the right groin, which was soft and grew with such rapidity that it was supposed to be an abscess. Incision, however, proved it to be a very vascular, round-celled sarcoma,

The disease grew rapidly, and the patient died of exhaustion in April, 1900.

Case VI.—Sarcoma of the Thigh.— Mrs. T., aged thirty-five years, with good family history. In May, 1897, the patient fell from a bicycle, badly bruising her right thigh. A lump appeared at the site of the contusion at once and never disappeared, but after about a week the patient noticed that it was increasing in size, and consulted a physician. The tumor grew rapidly, and in December, 1898, had reached the size of a man's head. It had no connection with the bone, and evidently started in the fascia.

Case VII.—Osteosarcoma of the Left Humerus.—I. D., male, eighteen years old: family history good. In the winter of 1899, a brick, which had fallen from the height of three stories struck the patient a glancing blow in the right deltoid region. A short time afterward the patient noticed pain in the region of the injury, and a little later a swelling appeared which gradually increased in size and was firmly attached. It seemed to be part of the humerus. Removal of the humerus and scapula was successfully performed by Dr. Russell S. Fowler of Brooklyn, in March, 1900. Within six months the disease recurred at almost the identical location in the other humerus and grew with great rapidity.

(To be continued.)

THE AKOUPHONE AND ITS LIMITATIONS.

BY J. A. KENEFICK, M.D.,
OF NEW YORK;
ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Mechanical aids to hearing devised in past years have been many and varied. The most efficient were constructed upon some well-recognized principle of physiological acoustics and were intended to reach the labyrinthine acoustic terminals by concentrating and intensifying sound waves either through the external auditory meatus or by conduction through the bones of the head or face.

No one apparatus has been found applicable to every case and the latest production in this line proves no exception to the rule. In proportion to the number of really deaf people those resorting to mechanical aids are comparatively few in number. This seems to be accounted for by two factors, namely, the conspicuousness of these instruments and the intolerance of their aid by oversensitive acoustic nerves which are present in the great majority of afflicted individuals. The first is an objection which might be overcome by the cultivation of certain moral courage on the part of the patient while the second is a physical difficulty and as we shall see may prove a serious hindrance to the use of any mechanical aid based on the above principles.

The latest product of this kind is brought forward by Mr. Wilton R. Hutchinson, a young electrical engineer from the South, who has spent years of work and study in bringing the apparatus to its present stage of efficiency and has given us by far the most intense and powerful reproducer of sound and one whose possibilities exceed those of all similar devices.

Without going into a description of the mechanical construction of this contrivance, the details of which are for the most part trade secrets, the instrument may be considered as a telephone whose electric force is supplied by an ingeniously compact storage battery of six volts. The transmitter is fitted with one or a series of dome or funnel-shaped resonators for the purpose of gathering in and concentrating sound waves from all sources in its immediate neighborhood. Its receiver is so constructed that all sounds conducted to it are reproduced or retransmitted with such force and intensity as to produce a searching and sonorous wave of peculiar intensity and penetration which is magnified still more on account of the closure of the external auditory meatus by the instrument which is held so as to completely cover it. The nature of this wave which gives a saw tooth character to its tracing is not yet understood.

In ordinary use the storage battery is carried fastened at some convenient place about the body, while the transmitter or wave collector may be held in the lap or laid upon a table. The receiver is fitted with a handle of suitable length so that it may be held in close contact with the ear with its vibrating diaphragm directly over the external meatus. This receiver is to a certain extent under control and the intensity of its action adjusted either by manipulating the adjustment of the diaphragm or by means of a sliding switch on the handle and manipulated by the patient's finger.

This is the outfit ordinarily recommended for the partially deaf. When used at the opera or lecture its transmitting end is reinforced by adding an increased number of wave gatherers, its receiving end being adjusted as nearly as possible to the toleration of the patient's auditory apparatus. When used for the instruction of deaf mutes a special transmitter is used and the receiver again adjusted to the comfort of the subject's hearing apparatus.

Deaf individuals who seek mechanical aid for their affliction (commonly without the aid or advice of an aurist) come generally under one of the following headings: (1) Those whose membrane and ossicles are intact, but functionally embarrassed by sclerosis or injury while the nerve is yet free; (2) those whose conducting apparatus is embarrassed by the absence of the ossicles or the greater part of the tympanic membrane, the nerve remaining free; (3) those in whom there has been disease involving, but not wholly destroying the labyrinthine nerve terminals—deaf mutes; (4) those whose deafness is

caused by destruction of the nerve function somewhere in its central course.

In the first class of cases we find in the great majority of cases flaccidity of the tympanic membrane and hyperesthesia of the acoustic nerve. The tensor tympani in such cases has no function and consequently fails to protect the hyperesthetic nerve terminals in the labyrinth against these new sound waves. Add to this the possibility of obstruction in the Eustachian tubes and we have with the receiver held close against the ear a condensation of sonorous waves of such intensity as to be practically unbearable. All noises in the immediate vicinity, such as the closing of a door or the shutting of a window, are here intolerable, and interfere with conversation in no uncertain way. To be sure the instrument is adjustable, but in these cases the nerve objects to the new stimulation even when at its lowest point of efficiency. It is well to remark in this connection that in some cases presenting a considerable degree of deafness, with symptoms of even labyrinthine involvement, such as vertigo and tinnitus, these alarming symptoms may depend upon purely mechanical causes and may wholly disappear after ventilation of the tympanum through the Eustachian tubes. Resort to any mechanical aid under these circumstances would be a serious mistake for such a patient.

When membrane and ossicles are both missing, and no involvement of the nerve is present, the patient being dependent entirely upon bone conduction, it would seem that the conditions were theoretically favorable for the use of the akouphone on account of the protection afforded the nerve terminals by the intervening bone. As a rule, however, such patients seldom resort to mechanical aids as they hear the loud voice fairly well.

In the third class of cases, which includes the deaf mutes, we find perhaps the greatest field for the practical use of this apparatus in teaching these unfortunates articulate speech. This was recently well demonstrated before the Otological Section of the Academy of Medicine, and judging from a single short lesson given to a deaf mute of eighteen years, who had practically never heard anything, it was easily evident that the articulation and even inflection of speech could be conveyed by these means to such individuals with a greater degree of success than has ever before been attained.

To the fourth class, with central lesions, no aid can be offered.

In judging the limitation of the akouphone as an aid to hearing the writer's opinions are as yet based largely upon theoretical considerations and upon the practical trial of a few cases of sclerotic middle-ear catarrh from his own and his colleagues' private practice.

This apparatus, although far and away the greatest resonator yet produced, is, from the aurist's point of view, still crude, its present method of application being a good deal like providing an arc light for an individual with failing eyesight without any regard to the conditions of his refraction or optic nerve.

It is to be hoped that the otologists everywhere will aid in developing and applying this apparatus according to the principles of their science to the end that its shortcomings may be mended and its possibilities extended.

In conclusion the writer would quote the following extracts from the pen of Mr. Alexander L. Pach which appeared in the *Silent Worker* for March. Referring to the akouphone or akoulalion he says, "To all the deaf who are able I would say, if you have a vestige of hearing and are able to make a personal trial of the appliance, not once or twice, but several times in succession, do not lose your head and forget that your sense of feel is something marvelous. Take into consideration that the noise children make when you are trying to read is so intensified that, though a hearing person might not mind it, it jars on you. . . . To all the deaf all over the globe who are looking forward to emancipation, I would say that there is hope that in time we may have a device that will enable us to hear, but that that time has not been reached."

29 West 36th Street.

CLINICAL MEMORANDUM.

PERFORATING GUNSHOT WOUND OF THE CHEST WITH FRACTURE OF BOTH BONES OF THE LEFT LEG AND LACERATED WOUND OF THE RIGHT THIGH: RECOVERY.

BY VICTOR COX PEDERSEN, A.M., M.D.,
OF NEW YORK;
ASSISTANT DEMONSTRATOR OF ANATOMY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND ASSISTANT SURGEON TO THE OUT-PATIENT DEPARTMENT OF ROOSEVELT HOSPITAL, NEW YORK.

The following instructive case occurred in the service of Dr. Robert F. Weir at the New York Hospital and is published with his direct permission, as illustrating the value of free use of sedatives in such conditions.

History.—A. J. H., U. S., thirty-one years old, single, bicycle policeman, admitted to the New York Hospital December 11, 1899. Three years ago his brother was in an insane asylum for three or four months following an injury to the head, and was discharged cured. Now follows the trade of machinist. In his mother's family several generations ago there was insanity also.

Personal Past History.—Indefinite, excepting as to typhoid fever fifteen years ago; severe attack with relapses, gradual complete recovery without sequelæ. Moderate alcoholic,

pronounced coffee habit. Always of nervous temperament. Early in June, 1899, suffered partial insolation; sick four days but hardly the same afterward; unable to stand heat, do hard work, sleep well; considerable mental anxiety and frequent severe frontal headaches with vertigo. These nervous symptoms did not abate after cold weather began.

Personal Present History.—Early in November, 1899, had persistent sleeplessness, while duties involved day work one week, night service the next. Hours for sleep were irregular and sleep when obtained not restful. Alcoholism is admitted by the family at this time, denied by the patient although he acknowledges having relied on alcohol in some form for support and taken more than was his wont. Became hyperneurasthenic, powerless to accomplish anything physical or mental, wretched digestion, very constipated, irregular bowels. Leading up to these conditions was the long strain of the Brooklyn Rapid Transit Company's strike, with extra work and irregular hours. Great exhaustion after it. Each officer was granted a five-day vacation, but that of the patient began December 5, 1899. His nervous state meanwhile became very bad. On returning from duty December 10th he had an attack of vertigo, unable to remember anything or obtain sleep, except after taking pills—not morphine—prescribed by the police surgeon.

The family describe the attempted suicide as follows: Arising December 11th, in a state of nervous excitement, he shot himself through the left chest; finding this effort futile, he jumped out of the window—third floor—upon an extension, rolled from this to the yard. He was admitted December 11th, at 7:35 A. M. Temperature 101.4° F.; pulse 116, small, thready, irregular. Respiration 30; profound shock, active delirium, abdomen flaccid, left chest less active than right. The ambulance surgeon administered Magendie's solution (mix) on reaching case and mv more in the reception ward with atropine sulphate, gr. $^1/_{100}$, strychnine sulphate, gr. $^1/_{20}$, and stimulating enema of whisky. Reached ward 7.45 A. M.

Physical Examination.—This showed wound of entrance fifth space, 3½ inches out, apparently just missing upper border of sixth rib and apex; wound of exit, eleventh space, 4½ inches out, on left side. Clothing and skin both burned about the former. Left chest limited in action, indefinite signs of fluid in infrascapular and infra-axillary regions. Pericardium not examined. Heart acting well. Abdomen slightly rigid, no distention. Simple complete Pott's fracture at left ankle. Large lacerated wound in the right thigh almost reaching the bone through the vastus externus and biceps, admitting probe upward about 6 inches, and almost accommodating the hand in its cavity.

Treatment.—Gunshot wounds were covered with 1-5,000 wet bichloride dressing; laceration irrigated clean, packed and covered with the same. Fracture left in temporary ambulance dressings. Strychnine sulphate, gr. $^1/_{30}$, every three hours hypodermatically. Atropine sulphate, gr. $^1/_{100}$, for respiration of 12 per minute or less. Heat to surface. Continuous hot rectal irrigation. Soon abandoned as seemed to disturb patient. Elevation of foot of bed. Nothing by mouth, except small quantities of cracked ice sucked through compress. At 3 P. M. examined by Dr. Weir. Abdomen rigid, distended, tender and tympanitic. Perforation of stomach suspected. Operative interference contra-indicated by general condition. Patient to be kept quiet absolutely with morphine.

Temperature during the first day, December 11th, rose to 104.6° F.; pulse ranged from 116-160; respirations 30-40. No food. Morphine (Magendie's m xxix total). Slept little, but much quieted. General condition declining.

Second day, December 12th, nutritive enemata q. 4. h., were well assimilated. Very small quantities of boiled water by mouth. Urine negative. Examined by Dr. Weir and Dr. Bull, perforation of stomach with onset of peritonitis suspected. Operation contra-indicated. Ice-coil to abdomen. Boiled water stopped, replaced by small quantities of brandy and water, every half-hour. Magendie's solution, m x total. No dressings as patient to ill to be disturbed. Remained quiet, sleeping at intervals. Dr. Peabody also saw patient during the day, concurred in probable diagnosis and treatment and established existence of fluid in left chest and probably pericardium in small quantity. Temperature reached 104° F. and above all day, falling, late in the night to 102.2° F., pulse 120-160, respiration 18-32.

Third day, December 13th, general condition much better. Enemata assimilated. Ice-cap to head for pain. Volkmann splint to leg. Thigh wound packed with iodoform gauze in bichloride, 1-5000 solution; changed later to large Mikulicz dressing of sterile gauze in Thiersch's solution and covered with rubber tissue. During the night patient drank copiously from the ice-coil tube in spite of attendants. No bad results. Hence diagnosis of gastric perforation abandoned and mouth feeding began; clear soup, 5ii, q. 2. h. cracked ice and boiled water allowed. Total Magendie's solution, m xxiii. Temperature 100.6°-102.2° F.; pulse 102-140; respiration 20-32.

Fourth day, December 14th, generally stronger, much better. Mouth feeding increased, rectal feeding, every six hours. Heat to surface stopped. Nitroglycerine, every three hours, gr. $^1/_{50}$, hypodermatically. Dressings as before. Slept fairly well and long. Total Magendie, m x. Temperature 101°-102° F.; pulse, 90-120; respirations 24-28. Slept well at intervals.

Fifth day, December 15th, signs of peritonitis disappearing. Ice-coil stopped. Treatment otherwise the same. Magendie's solution, total ℥ xiii; slept well. Much improved. Temperature 101°-102.4° F.; pulse 96-120; respiration 24-28. Dressings same.

Sixth day, December 16th, large sloughing mass removed from thigh; 1-100 carbolic acid wet dressing applied. Full fluid diet. Rectal feeding stopped. Temperature 100.6° to 101.8° F.; pulse 92-116; respiration 20-24. Sleeping much better and for longer intervals. Total Magendie's, ℥ xviii.

Seventh days, December 17th, all conditions same. Slept very little, Magendie's solution, total, ℥ viii. Temperature 100.4° F. to 102° F.; pulse 84-100; respiration 16-32. Still gaining.

Eighth day, December 18th, irrigation of thigh wound begun, otherwise dressing the same. Morphine, gr. ¼; codeine, gr. 1; trional, gr. xx, as sedatives, slept quite well. All other conditions about the same. At no time was there hematemesis or hemoptysis. The management of the pistol-shot wound was daily changes of the wet dressings, followed by dry sterile dressings and aristol powder. Neither wound suppurated. The entrance cast off a few small sloughs. Otherwise they healed promptly. The laceration was treated in the usual way, and healed well after two abscesses developed in the thigh high up. The fracture united in good position and with full function after the usual plaster splint.

Skin grafts on the thigh wound were made January 15th; one-half succeeded. The wound healed fully leaving function fair. The patient was allowed to sit up, on chairs, on January 27th, and February 10th (about) was permitted to use crutches. He was discharged May 8, 1900, cured.

Heart, pericardium and abdomen negative, left chest showed few signs of thick pleura. Right thigh had a small sinus persisting. Throughout the acme of the condition enough sedatives, morphine, etc., was given to procure absolute quiet and to remain just within actual deep sleep. The patient could be aroused for his medication, but otherwise was indifferent to his surroundings though not really asleep. This forced quiet appears to have saved his life.

MEDICAL PROGRESS.

Ice-Bags in Lobar Pneumonia.—George L. Collins (*Boston Med. and Surg. Jour.*, March 28, 1901) reports in detail nine cases of lobar pneumonia in which cold was applied by means of ice-bags. He summarizes the cases as follows: In only one case did the ice-pack cause discomfort. In not one case was the crisis accompanied by dangerous collapse. The ice-pack was used to abort cases just beginning, in cases with well-marked signs, and in cases showing resolution. Accompanying signs of bronchitis were not considered contra-indicatory. The indication for the use of the ice-pack was in each case high temperature, and not physical signs. The ice-pack was removed only when the temperature became lower. The average fall of temperature was 4.5° F. This fall occurred in all but one case within forty-eight hours after applying the ice, in most cases it was within twenty-four hours. The white corpuscle count invariably began to fall with the temperature, and reached normal in about one week after the temperature became normal. The ice had no effect apparently upon the physical signs.

Malignant Syphilis and Zittmann's Decoction.—In very malignant cases of syphilis that prove rebellious to the influence of mercury or the iodides Granville MacGowan (*Jour. Cutaneous and Genito-Urinary Dis.*, March, 1901) recommends the use of the decoction of Zittmann. He reports, in detail and with photographs, a case in which this decoction was very efficacious. In the preparation of this decoction the writer follows the original formula. The decoction spoils easily and should be kept in an ice-chest. The following formula is for enough to last for from six to ten days. Bruised sarsaparilla root ℥iv, water ℨ 280; (Package No. 1) Fennel seed, anise seed, aa grs. 80, liquorice root (cut), senna leaves, aa ℥ss. Digest the sarsaparilla root in water for twenty-four hours, then add package No. 1, and bring to a boil, while suspended in it in a linen bag is: (Package No. 2), Powdered alum, powdered white sugar, aa ℥ii, calomel grs. 80, cinnabar, grs. 20. Boil gently until the quantity is reduced to a gallon, or a little less, then strain through a fine cloth, and put up in bottles holding a little more than a pint each. Label this: Zittmann's Decoction, No. 1. To the dregs of this decoction add the contents of package No. 3, consisting of cardamon seeds, cinnamon bark, liquorice root, aa ℥i. Pour in ℨ 280 of boiling water, and cook to a gallon. Strain, and bottle as before. Label: Decoction, No. 2. The writer directs that both the stronger, No. 1, and the weaker, No. 2, be given each day, the first for its purgative and diaphoretic effect, the second for its diuretic properties. The taste of these mixtures is not very nice, but the nausea caused by them, when given in large quantities, can be overcome. MacGowan uses these as follows: The patient takes a light breakfast at 7 A. M., and at 9 A. M. four ounces of the stronger decoction as hot as he can drink it. This dose is increased one or two ounces each day until he is taking as near a pint as he can without vomiting. This dose will purge the patient two to four times a day. He has a light lunch at 12.30 and at 3.30 P. M., while in bed, takes from half a pint to a pint of the weaker decoc-

tion, cold. Later the patient has an alcohol rub, and at 6 P. M. a good dinner, without any green vegetables or fruits. No mercury or other drug is used while the decoction is being given. Early in the second week the improvement will begin to be visible. In the fourth or fifth week the patient will be on the highroad to recovery. When the patient's nails and ear lobes are pink, and the eye clear, mercurials can be employed to finish the cure.

Bottle in the Rectum.—W. M. A. Anderson (*Brit. Med. Jour.,* March 9, 1901) reports a case in which a glass bottle was found bottom upward in an adult rectum. He prepared to do a posterior median proctotomy back to the sacrum and coccyx in order to remove it, but first tried traction with a uterine ecraseur, whose wire had been bent to a right angle with its axis. At first the bottle did not move. On exploring with the finger he found that the concave bottom was acting as a sucker and resisting. When air was admitted beyond it, the bottle slipped out. Passed in with the aid of much vaseline, the bottle was of such size as to fill the bowel and cause great pain.

Ethyl Chloride as an Anesthetic.—W. J. McCardie (*Lancet,* March 9, 1901) says that ethyl chloride has the following advantages as an anesthetic in minor surgery and some of the shorter procedures of major surgery and gynecology, such as involve anesthesia for about thirty minutes or less: (1) Rapidity of its action and (2) of its recovery, each being about two minutes, (3) almost total absence of after effects, (4) safety in cardiac, renal and pulmonary disease when ether and chloroform are contra-indicated or dangerous. Its main disadvantage is that except in children muscular relaxation is not marked and rigidity may be present to a great degree. The Brener mask obtainable in Vienna is the best for its exhibition.

Recent Notes on Treatment of Diphtheria.—Fenn of Manchester, in the February number of the *Journal of Laryngology,* gives a chapter of notes reviewing recent papers on the treatment of diphtheria. Eyre has found in milk supplied to a school the short pathogenic or sheath variety, as well as the Klebs-Loeffler bacillus; and Macfarden and Hewlett found bacilli in the throats of pigeons identical with the Klebs-Loeffler bacilli except as to their pathogenic and toxic properties. Richardière and Tollemer found virulent bacilli floating in dust of the air in a diphtheria hospital and which had not been disinfected for several weeks. They were absent after disinfection. Trevelyan found diphtheria bacilli in cases of stomatitis with membrane without general symptoms. The value of antitoxin is now generally admitted by the medical press by both statistical evidence and clinical observation, in both hospital and private practice. In Queensland the death-rate in five antitoxin years is little more than one-third of previous records. In Chicago of 4,071 cases in three and a half years treated with antitoxin only 0.77 per cent. died. In the Children's Hospital at Brisbane, there was reduction of mortality from 42.2 per cent. to 12.6 per cent. Goodall shows that in the Metropolitan Asylums Board Hospitals for 1896 and 1897 a high mortality of 50 per cent. was reduced under antitoxin to 5 and 4.1 per cent. for these two years. The most forcible objection to statistics is their inclusion of cases only bacteriologically recognized as diphtheria. This cannot hold for laryngeal cases. In these latter, whose diagnosis is the same as before, under antitoxin treatment there is less need for tracheotomy. The mortality in hospital cases has been reduced from two-thirds to one-fourth of the cases operated on. Goodall says: "Whereas, in the pre-antitoxin days of 100 tracheotomies you could not expect to save more than 29, now you can expect to save no fewer than 53; of laryngeal cases not operated on, in those days not more than 48, now not fewer than 75; of all cases (operated on or not), then not more than 34, now not fewer than 49." There has been a tendency to increase the dose of antitoxin. Turner has given 6,000 to 12,000 units for a dose. Biernacki in one case gave two doses each of 18,000 units within fourteen hours. "Antitoxin should be given for effect, and most assuredly not for specified doses." All evidence calls for early administration. In the 4,071 cases treated in Chicago, the mortality of those treated on the first day was only 0.28 per cent., of those treated on the fourth day 11.39 per cent., of those treated after the fourth day 25.37 per cent. Statistics of Goodall and Turner teach the same lesson. Tonkin in 200 cases found mortality 3 per cent. for those treated in first three days and 12 per cent for all the other cases. Post-diphtheritic paralyses have increased since introduction of antitoxin. This is explained by the survival of serious cases which in the pre-antitoxin days would not have lived. The type of paralysis has become on the whole less severe, at all events less fatal. Goodall states that of 1,580 cases of paralysis after antitoxin treatment, only 5.7 per cent. belonged to those treated on the first day, and 10.1 per cent. to those treated on the second day, and "only one case of severe paralysis occurred among those treated on the first two days with no death from paralysis, whereas 51 severe cases and 3 deaths from paralysis occurred among those who were not brought under treatment till the fourth day or later. . . . There is some evidence that large doses, *i.e.*, not less than 4,000 units of antitoxin, are more effective than small ones, both in preventing paralysis and in reducing the mortality due to it." Antitoxin reduces the likelihood of the occurrence of nephritis. With early treatment albuminuria may not appear and will soon disappear. At the Brisbane Hospital local throat treatment has been abandoned. Bolton found bronchopneumonia,

nephritis and other inflammations and also sudden death follow injection of antitoxin, but nothing of this kind has occurred in the London hospitals. He believes the incidence of albuminuria is increased by antitoxin, but the condition is transient and slight. "The complications of antitoxin are at times very painful and inconvenient, but quite harmless." Causes of failure are, as given by Trevelyan, (1) its too late administration; (2) its sufficient dosage and strength; (3) presence of mixed infection. The controversy as to the utility of antitoxin is well-nigh closed, and "those practitioners who neglect or refuse to use this remedy in suitable cases are in so doing assuming a grave responsibility."

Non-Operative Cases of Acute Mastoiditis.—Gorham Bacon (*Archives of Otology*, February, 1901), reports the histories of forty consecutive private cases of acute purulent otitis media complicated by acute inflammation of the mastoid cells. Radical operation was necessary in 10 cases. In 2 of these 10 a subsequent operation for sinus thrombosis, one proving fatal. In 30 cases, or 75 per cent., the mastoid cells were not opened. The patients varied from six to sixty-five years of age. A great many cases of mastoid disease can be cut short in the first stage, if, instead of administering opiates to relieve the pain, or perhaps phenacetin or quinine to reduce the temperature, we apply leeches at once." A leech, natural or artificial, is best applied just in front of the tragus. Patient should be put to bed with little to eat, calomel given and tincture of aconite in drop doses, if high fever. If the mastoid process is tender on pressure, the Leiter coil should be applied and the cold should be kept up for at least forty-eight hours. Meanwhile, as soon as there is bulging of the drumhead "a free incision should be made in the membrane along its posterior border, from a point behind and below the stapes to the lower border of the drumhead, and close to the bony canal. . . . In all cases of scarlet fever, measles, diphtheria, influenza, and especially when the infection is due to the streptococcus or pneumococcus, it is advisable to make an early incision in the drumhead." After this douche the ear frequently with a warm boracic-acid solution (℥i to ℥viii), or bichloride (1 to 3,000), to promote the discharge. A free incision should be made where the spontaneous rupture is too small. Sometimes, even when operation on mastoid seemed imminently unavoidable, a further free incision has decided the recovery without further interference. The writer is not opposed to the mastoid operation, but finds he has fewer cases requiring it since he has adopted this plan of treatment. If, after employing above treatment and finding that the temperature remains elevated after a profuse discharge, there is still tenderness over the mastoid, then operation upon it may be unavoidable. This is all the more likely to be the case with streptococci and pneumococci in the pus from the tympanum. The lungs should be examined for pneumonia. Strict and daily watch should be kept for first indications for opening the mastoid whilst doing all possible to avoid that step.

Sexual Irritability of the Male.—It is said that 25 per cent. of all men are at some time affected with what is called sexual irritability. A. Sander (*Indian Med. Rec.*, Jan. 30, 1901) divides them into three classes; one belonging to the lithemic type, being usually fair, large stature, flabby muscles, and although appearing healthy their powers of elimination are defective and their urinary tract is thus irritated. The second class is the nervous type, inclined to a great variation of emotional excitement. Their sexual desire becomes an uncontrollable factor like various other impulses of their unstable nervous system. The third class comprises those in which gonorrhea has been the efficient cause. For the first and second classes the first requisite is a moderate and regulated amount of exercise, such as walking in the open air. The lithemic are frequently benefited by considerable exercise while irritability may be kept up by undue physical exercise on the part of the "neurasthenic." The diet of the lithemic should be principally of fruits and green vegetables—avoiding too much meat, coffee and alcohol. Fish and poultry are good. To aid elimination he recommends:

℞ Sod. et pot. tartrate.....60.0 (℥ij)
Pot. tartrat. acid.....30.0 (℥j)

M. et. Sig. One teaspoonful in water each morning.

To allay the sexual passion of the neurasthenic one-dram doses of fluid extract of salix nigra one-half hour before retiring are usually effective. As a nerve stimulant arsenic in combination as:

℞ Fowler's solution ..... 4.0 (℥j)
Fl. ext. ergot..... 12.0 (℥iij)
Tr. capsici ..... 0.8 (♏x)
Glycerine ..... 30.0 (℥j)
Aquæ .....240.0 (℥viij)

M. et Sig. Half an ounce three times a day after meals.

Arthritic Edema of the Eyelids.—These transient edemas which come on without warning, last a few hours, then disappear to come again in the same way, without coincident fever, albuminuria, or cardiac lesion are usually attributed to anemia, scrofula, angioneurotic phenomena, nervous explosions, etc. Gaillard reported two cases, one following an attack of peliosis rheumatica, the other just preceding an attack of true articular rheumatism. A. Trousseau reports five cases (*La Presse Méd.*, Mch. 6, 1901) four in young girls in whom each appearance of this edema was followed by acute articular rheumatism, and the other in a man of forty-two years, afflicted with gout. He has seen the edema alternate with that of other regions especially of the genitals, and with other skin manifestations, erythema, eczema, etc.

Active Principles of Digitalis.—There seems to be an almost hopeless confusion about the relative values of the various glucosides of digitalis. One difficulty arises from the fact that the German preparations are derived from the seed, while our official drug is the leaf. J. W. England (*N. Y. Med. Jour.*, April 6, 1901) says that digitoxin is extremely irritant, frequently producing abscesses when used hypodermically and requires several hours to produce its effect. He has prepared a "tincture of fat-free digitalis" made by exhausting freshly-ground digitalis leaves with pure benzin, percolating with diluted alcohol and neutralizing with ammonia water. All the proximate principles are made soluble in water and not partly so as in the official tincture. This is an important feature for all compounds must be made water-soluble before they can be absorbed. Experiments have shown that this preparation acts quicker than the ordinary tincture, in from fifteen to thirty minutes, and hence is considered a more valuable mode of administering the active principles of digitalis. Digitoxin usually requires five to six hours, to produce cardiac or renal symptoms and is very slowly eliminated and hence is not looked upon as the most valuable therapeutic principle of digitalis.

THERAPEUTIC HINTS.

Acute Articular Rheumatism in Children.—In children the salicylates must be used sparingly and are best given in large doses continued for only a short time. Used thus they may give prompt relief, but both stomach and heart must be watched. Rest in bed is the only safeguard against endocarditis, and when this is established opium should be used in small dose. Alkalies should follow the use of salicylates. For the extreme anemia peptomangan and open-air exercise of such a nature as to strengthen the heart are indicated.—*F. C. Simpson, in Pediatrics*, April 1, 1901.

Alcohol for Children.—In the acute infectious diseases, the nutrition is maintained by the power of alcohol to prevent nitrogenous waste, animal heat is regulated by opening up the peripheral circulation, and the energy which is depressed not lost, as from the heart weakened by fever, is restored. Especially in those bad cases of diphtheria with sepsis or bronchopneumonia, or the septic nasolaryngeal cases in which antitoxin is of little avail, whiskey in conjunction with iron and mercury to give support, not stimulation, will directly save life.—*A. E. Bieser in Pediatrics*, April 1, 1901.

Antistreptococcus Serum. — Labusquière (*Annales de Gynécologie et d'Obstetrique*, March, 1901) reports twelve cases of puerperal infection treated by Blumberg with the serum of Marmorek. In nine cases the lochia was examined bacteriologically. One severe case showed pure culture of anaerobic diplococci, no immediate result from injection, but subsequent cure. Case II. showed bacilli streptococci, and other cocci, and the patient died. Case III. had been seven weeks ill, and the lochia contained bacilli and anaerobic streptococci. This patient also died. In Case IV. with mixed infection the temperature began to fall the day after the injection, and was normal on the third day. Case V. was of mixed infection and, though ill for four weeks was apparently cured by one injection. Cases VI. and VII., with sterile lochia, the one having been ill for five days, the other for thirty-nine days, responded promptly to the serum. Cases VIII. and IX. gave pure streptococcus culture, the one responding directly to 20 grams (5vj) of serum, relapsing when the serum was discontinued after two injections, and progressing to recovery when the injections were resumed, the other showing no immediate change of symptoms, or fall in temperature, but gradually recovering. In three cases no bacterial examination was made and all were cured, though in one the injection was not used until the temperature had begun to break. A diffuse erythema, or a painful, red erysipelas-like area about the site of injection sometimes appeared, and in one case an erythema multiforme. The injections caused no albuminuria, but were followed for a single day by a good diazo-reaction.

Pneumonia and Empyema.—When pneumonia is complicated by empyema before resolution has taken place, Philip Marvel (*Therapeutic Gazette*, March 15, 1901) advises against evacuation till the crisis has passed, unless the embarrassment to the breathing and circulation or evidence of danger from the toxemia should be such as to render relief imperative.

Silver Salts in Nasal Catarrh.—E. B. Gleason (*Therapeutic Gazette*, March 15, 1901) recommends for atrophic rhinitis, spraying the nose once or twice daily with Dobell's solution, and sniffing up every four hours a little stearate of zinc containing gm. 0.065-0.13 (gr. j-ij) of silver nitrate to each gm. 4.0 (5j). For exuberant granulations, scaring the stumps of polyps, etc., the nitrate of silver is too irritating, and the organic compounds should be preferred. If, however, a 12-per-cent. solution be painted upon inflamed tonsils and the inflamed lateral wall of the pharynx, a sense of great comfort follows. Painting thus two or three times a day is one of the best methods of aborting acute pharyngitis and tonsillitis, any affected tonsillar crypts having first been freed of pseudo-membrane. Hay-fever and nasal hydrorrhea are best treated locally by a spray of adrenalin, 1-5,000, or of 10-per-cent. aqueous extract of dried suprarenal every two hours or by pledgets of cotton soaked in the solution and placed within the nose.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 13, 1901.

DELAYED WIDAL REACTION AND TYPHOID RELAPSE.

The Widal test has not entirely fulfilled the hopes held out by its discoverers. Certain cases of typhoid fever even in Widal's own hands failed to give the characteristic reaction though typhoid bacilli were afterward found in blood withdrawn from the patients' spleen. On the other hand the blood of the normal individuals and of some patients suffering from diseases other than typhoid fever, and without typhoid fever in their histories, has proved to be possessed of the agglutinative power. These reported pseudoreactions, however, grow fewer and fewer in number as the exact conditions necessary for the proper accomplishment of the test come to be better understood and are more perfectly complied with.

Widal's reaction is, however, a most useful diagnostic auxiliary and as it has come to be employed more and more, it has proved to be of value in originally unanticipated ways. Certain affections that clinically bear not the slightest resemblance to typhoid fever and were not suspected of being even remotely connected with it have been proven recently to be due to the typhoid bacillus. Pneumonias, and meningitis constitute the most important types of these extra-intestinal typhoid fevers that have been running their course often to a fatal termination without a suspicion of their true bacterial origin.

One of the most inconvenient properties of the Widal test has been its tendency to give negative results in certain cases until very late in the disease. Sometimes the presence of the agglutinative power in the blood cannot be demonstrated until convalescence has been established or even until a normal temperature has existed for some time. The reason for this delay in the development of the characteristic agglutinating property is not understood. Of course there are many other things about the Widal test that are but ill understood and the problems involved demand serious study with the promise of fruitful results. When Widal first proposed the test he said that he was not decided himself as to whether the agglutinating power of the blood serum of typhoid patients was a manifestation of infection or immunizing reaction. From the frequent occurrence of the reaction in the early stages of the disease—the second week and sometimes earlier—he seemed inclined to consider the agglutinative power a phenomenon of infection.

Later the trend of opinion has been toward classing agglutination as a protective reaction —a manifestation of bactericidal power. Recent observations on the protective power of mother's milk would seem to confirm this view. The young of animals born from mothers, in whom artificial immunity to the influence of certain bacteria has been produced, are not immune by the fact of birth. If suckled by immune animals, however, they often acquire immunity. This immunity may not last for more than a few days after suckling ceases. It is well known that the power to produce agglutination of the typhoid bacilli may be conveyed through the milk of a mother in whose blood the reaction exists as the result of a past attack of typhoid fever. The reaction ceases to be present, however, in the blood of the child very soon after nursing stops. It endures at most for a week or two. In this there is a striking analogy to the artificial immunity to microbic action which is conveyed by the milk.

If we assume, then, that the Widal reaction is a manifestation of beginning immunization of the organism to the disease it will be readily understod that the delay in the appearance of the agglutinative power in the blood serum means the failure of the attacked organism to react in time for its own protection against the typhoid bacillus. In a number of reported cases the occurrence of the Widal reaction late in an attack of typhoid fever has been followed by a relapse of the disease. The organism had not at the end of an ordinary attack of typhoid fever sufficiently immunified itself to protect it from germs that invaded hitherto unaffected intestinal follicles.

This subject is as yet in need of investigation. The Widal test is by no means simply a positive or negative answer to the question, is typhoid fever present? It may prove to be a valuable prognostic measure that will point out the failure of immunization and the consequent danger of relapse. Its practical importance from this standpoint can be scarcely exaggerated. A delayed Widal reaction will be the indication for exercise of the greatest care in the resumption of ordinary diet. Relapses will not come as the surprise they have been heretofore and the practitioner will realize during the course of the first attack the necessity for the conservation of the patients' strength.

DEATH OF THE CHRISTIAN SCIENCE BILL.

The Christian Scientists are audibly giving thanks for the power of prayer, and secretly for the power of the dollar. Seldom has lobbying been more persistent and more to the point than in the suppression of Mr. Bell's Anti-Christian Science Bill. And for good reasons; a business like that of Mrs. Eddy's is not to be lightly given up, nor a profession so easily acquired as that of the healing art by absent treatment to be set aside for the lack of a little judicious guidance in the lobby.

Had the medical societies been a little more alive, and a little less argumentative they might not have raised so many objections, and the bill might have gone through. As Mr. Bell said in explanation, "The New York County Medical Society and the New York County Medical Association diagnosed the case differently, and while they were quarreling among themselves, refusing obstinately to call into consultation legislative experts, the patient expired."

The trouble lay partly in the fact that no one knew just how to word a bill that would give every competent physician and druggist the right to carry on his profession, and at the same time put an end to the impostures of quacks of all grades. The element of faith and religion, that is so often the only impressionable component of a woman's mental caliber, stands out against the element of justice and common sense that characterizes most men in the medical profession. It is impossible to legislate emotions out of a woman, but it would not be impossible to protect, by a legislative act, the community from the effect of these emotions. To do this our fellow physicians, even at the risk of being thought unethical, must do battle with the absurdities that are being taught, and give lectures and write and generally express themselves on the subject of their profession. Dr. A. H. Smith and Dr. A. Jacobi, in discussing the "Duty of the Public to the Medical Profession" at the Academy of Medicine last week, both took the same stand as Dr. Lydston, whose paper was published in the Medical News of April 6th, that the medical man can help the public and the profession at large by bringing them into closer relations, and by educating the people to a correct appreciation of the merits of scientific medicine.

A PLEA FOR PROFANITY.

As Dr. John Brown finds a saving grace for little Marjory Fleming in the lack of the final "*n*" in her Dam! so Professor G. T. N. Patrick finds an excuse for mankind at large in the matter of profanity, by running it down to its primitive origin.

In his article, "The Psychology of Profanity," in the March number of the *Psychological Review*, the history of the race shows that most profane ejaculations are the fossil remains of religious terms or ejaculatory prayers, and that the history of profanity is bound up with the history of religion. That this has always been considered a deplorable state of affairs is shown by the punishment prescribed from the days when it was death in the Levitical law, till in the seventeenth century it was twelve-pence an oath in England. In those days "Goddam" was a mere nick-name for an Englishman, proving the inefficiency of legislating on matters of personal morals. The simple feeling that swearing is poor taste has made swearing unfashionable; but has not so eradicated the tendency, but what Pro-

fessor Patrick has found material enough to work out the answer to these two questions, "Why do men swear?" and "Why do they use the words they do?"

People swear when they are provoked, or angry, or surprised, or hurt, and it has been observed that the most dangerous men are not the hardest swearers. Where there is great emotion accompanied by great helplessness men swear. Philology shows us that swear words are the old forms of spoken language, and physicians find that in progressive aphasia profanity is often the last form of speech to be lost. Evidently, then, profanity is an ancient and deep-seated form of expression.

So far do the psychologists agree; but when it comes to the *why* of swearing they hold different opinions. Some hold that the emotion of anger necessitates the escape of the surplus nervous energy, and that when one inhibits the natural and primitive impulse to battle, this energy bursts forth through the organs of speech in the form of oaths. As such profanity is supposed to have a purifying effect on the system just as a "good cry" relieves the tension of anger.

Others hold that profanity is but a series of steps from the growls of animals who are in terror and who wish to strike terror. The angry primitive man tries to shock his enemy by calling on thunder and gods, and the angry modern man consigns him in tones of awful wrath to eternal punishment. When one gets a German accumulative oath like *Alle Weltkreuzmohrentausendhimmelsternundgranatensakrament*, one wonders who could stand before it. From the shock of terror there came the shock of temerity in taking holy names in vain, so that the greater the reverence of names of saints, or places, or deity, the greater is the shock to the man sworn at and supposedly the greater the relief to the man swearing.

WATER WAYS AND CONTAGIOUS DISEASES.

The inauguration of a suit in chancery about to be brought by the Passaic Valley Protection Association for the monumental sum of $10,000,000 against the city of Paterson calls attention to an important sanitary problem and to its medico-legal aspect.

For years the city of Paterson has been dumping its sewage, without modification, into the Passaic River where it has been carried to many towns below it and three given rise to numerous cases of typhoid fever. The citizens living along the banks have therefore made themselves into an association for mutual protection and, by claiming extensive damages, hope to be able to compel the city of Paterson to take proper care of its sewage.

It would appear that in this enlightened era of sanitary science and humanitarian doctrines it should not be necessary to resort to legal means to compel a city to protect its neighbors, but corporations are said to be lacking in consciences and municipalities may need the sting of heavy damages to pay in order to compel them to make concession to the rights of others.

We commend the Passic Valley Protection Association in their action and trust that in the righting of their wrongs others, suffering similarly, may profit.

ECHOES AND NEWS.

NEW YORK.

Society of Medical Jurisprudence.—At the 158th regular meeting of this society, held Monday, April 8th, Dr. J. B. Huber read an interesting paper on "Faith Cure and the Laws."

Rochester Academy of Medicine.—The regular meetmg of the Section on Surgery was held April 10th. Drs. Henry H. Covell, George E. Beilby, Edward W. Mulligan and Henry J. Williams presented interesting cases, and Dr. John W. Whitbeck read a paper on "Cancer of the Pylorus."

State Charity Board.—It is announced authoritatively that the bill to reorganize the State Board of Charities has been abandoned by its supporters. It was drafted and introduced at the instigation of Governor Odell, who, it is understood, has consented not to have it pressed, in view of the excellent reasons advanced by important and responsible interests, urging a continuance of the existing administration of the State's charities.

Reprint of Ephemeris.—For a number of years Dr. E. H. Squibb of New York has made a résumé of the modern advances in materia medica, pharmacy and the collateral sciences. This has been printed from time to time with other matters of cognate interest as the Ephemeris. This year No. 3 of Vol. 6 has been reprinted and termed the *Supplement to the State Medical Association Journal.*

Clinical Lectures on Hydrotherapy.—The trustees of the Riverside Association announce that the Medical Director of the Hydriatic Department, Dr. Simon Baruch, will give a course of lectures on Practical Hydrotherapy, on Thursdays at 2.30 P.M., at the Association

House, 259 West 69th street. The course is free to the medical profession.

New Anti-Hypnotism Bill.—The Senate Committee on Public Health reported on April 4th a substitute for the bill of Senator McCabe to regulate the practice and teaching of hypnotism, mesmerism, suggestive therapeutics, and other kindred practices. The substitute relates only to hypotism and mesmerism, and provides that any person who practises these who is not a duly licensed physician or graduate from an educational institution for the teaching of such practice, duly licensed by the Regents of the State, shall be deemed guilty of a misdemeanor.

The Doctors and the Vice Crusade.—Seven members of the County Medical Society have been appointed a committee to investigate the evils of prostitution in the tenement-houses from a physician's point of view. The committee consists of Dr. P. A. Morrow, Dr. S. A. Knopf, Dr. H. D. Chapin, Dr. C. W. Allen, Dr. L. D. Buckley, Dr. Ludwig Weiss, and, ex-officio, Dr. George B. Fowler, President of the society. It met for the first time on Thursday evening and organized with Dr. Morrow as its Chairman. After its work is further under way, it will communicate with the Committee of Fifteen; but its investigation will be wholly along lines which concern the physician as a practitioner.

Home for Scientific Alliance.—Plans have been drawn and a subscription of $25,000 has been received for a building intended to house the allied scientific bodies included in the Scientific Alliance. The plans contemplate a building costing $300,000 built upon a plot costing $200,000. The building is intended to furnish facilities for original research and for the proper housing of the valuable libraries of the various societies which are now scattered. There will be an adequate lecture room and meeting rooms for the different bodies in the alliance.

Elmira Reformatory Superintendency.—There is a bitter fight on for the Superintendency of the Elmira Reformatory. Dr. Frank W. Robertson is at present Acting Superintendent. If Patrick J. McDonnell, at present Assistant Superintendent of the reformatory, has his way, however, Dr. Robertson will be ousted very soon. Mr. McDonnell, before he came to Elmira to accept a position at the reformatory, was head keeper of the Erie County Penitentiary. A short time after Mr. McDonnell arrived at the reformatory, Dr. Robertson, it is stated, became jealous of his assistant. The Assistant Superintendent is a man who has had quite a deal of experience in handling criminals, while Dr. Robertson was initiated into prison work at the Elmira Reformatory. Dr. Robertson, before he came to Elmira, was attached to Bellevue Hospital as a physician. Dr. Robertson's home is in Owego, also the home of Senator Thomas C. Platt. Dr Robertson is on friendly terms with Senator Platt, and it is owing to the Senator's influence that the Doctor was enabled to secure a position at the reformatory. As the story goes, Dr. Robertson's jealousy of Assistant Superintendent McDonnell grew daily. The Assistant Superintendent has his eye on the superintendency, and Dr. Robertson knows it. Both men have been pulling all the political wires in sight to accomplish their ends. Dr. Robertson has the backing of Senator Platt, but the Assistant Superintendent is said to be in favor with three of the Board of Managers of the reformatory.

New Smallpox Hospital.—The request of the Board of Health for authority to expend $10,000 in the construction of a new hospital for contagious diseases on North Brother Island was taken up at a recent meeting of the Board of Aldermen and was defeated by a vote of 41 to 9, a vote of 45 in the affirmative being necessary to carry it through. All the Tammany men were in favor of the resolution, and Mr. McCall, the majority leader, said in a speech that unless there was relief at the contagious diseases hospital soon some of the patients would be obliged to sleep out of doors.

The Adulteration of Milk.—There are now pending before the courts in the various cities of the State, says the *New York Times*, a dozen or more cases brought to test the constitutionality of the provision of last year's law prohibiting the use of preservatives in milk. Among these cases is one against John S. Bieseker of New York City. This case was recently tried before the Appellate Division, and the law against the use of preservatives was declared unconstitutional. An appeal in this case has now been taken by the State to the Court of Appeals. Bieseker was represented by Herbert R. Limburger, who argued that if the law was sustained a man could not mix a milk punch without being guilty of a misdemeanor, since alcohol was a preservative of milk. Mr. Limburger's contentions being sustained by the court, other users of preservatives in milk, against whom actions have been brought in the name of the State, have engaged him to represent them.

The Bieseker case is one of much interest to the New York County Medical Society. Last fall this society took up the question of the use of preservatives in milk. The leading milk dealers of New York City were called into conference with the physicians. They all testified to the use of preservatives by the smaller dealers. Some of the preservatives used were chemically analyzed and were pronounced injurious to health. The opinion was advanced by some of the physicians who had given special attention to the subject that the infants of New York City were being poisoned by preserved milk, and that many cases of typhoid fever among the young and adults could be attributed to that source.

If the Court of Appeals sustains the decision of the Appellate Division in the Bieseker case, there probably cannot be new legislation to guard against the preservative evil until next year, which means that the poisoning of milk used by the poor in the big cities will continue during the coming summer.

Academy of Medicine.—"The Duty of the Public to the Medical Profession" was the topic under discussion at the regular meeting of the New York Academy of Medicine last Thursday. Incidentally the speakers also discussed the duties of the medical profession toward the public, and attempted to find the cause of what they considered the attitude of suspicion which the public always adopted toward any bill or reform measure advocated by the profession as a body. The question of how to bring about a change in this supposed public sentiment was gone into at some length by Dr. A. H. Smith, with whose ideas a majority of those present seemed to be in accord, to judge from the applause with which his remarks were received. "The science of medicine," he said, "is not in touch with the public at large because the profession has kept the public in ignorance of its work as much as possible." There is, of course, no such thing as a race of doctors, but they form a very close corporation, and every member of it shows what looks strangely like an instinctive desire to perpetuate the mystery which increased the dignity of the profession in days when it had little except mystery with which to command respect. They write extremely simple prescriptions in the fragments of a dead language intermixed with cabalistic signs, they resent lay criticism, and even lay description, of their work, and as much as they can they keep up the silly pretense that the opinions of followers of the same "school" never differ. Yet those of us who occasionally get hold of the medical journals and other literature of the profession have little difficulty in understanding what we read, and we look in vain for the big secrets which the doctors wear the air of concealing. They should forget the fact that their not very remote predecessors dabbled with what they imagined was the supernatural. Medicine is a great and noble art, and better men than the majority of its practitioners do not exist, but they have some antiquated ideas about professional ethics and dignity, and their belief that the modern public could not understand their work is a delusion. The modern public could not do that work, to be sure, but it has a perfect right to know as much about it as it chooses to learn, and the less mystery is made of it, the less will be the suspicion to which Dr. Smith referred.

Dr. A. Jacobi held similar views, and said that if the public could be made to understand that the medical profession was not a trades' union, or a trust, it would quickly respond in recognition of the profession's achievements.

All the speakers took occasion to denounce the Christian Scientists and the osteopathists and to propose various measures to prevent them from harming the public at large. In this connection Dr. D. B. St. John Rossa said: "I do not believe that that this struggle to pass new laws to bar out Christian Scientists and Osteopathists is necessary. If we should carry a case to the higher courts we would probably get a decision that they are practising medicine illegally under the present laws."

Dr. Rossa also advocated the passage of a law giving the medical profession a voice in all legislation affecting medical science and the public health. Dr. W. H. Thomson declared that the public, and not the doctor, should decide this question, because the physicians would be accused of selfish motives.

"The practice of calling 'healers,' he said, "especially in the case of contagious diseases, is more dangerous than letting children play with fire. Their whole doctrine is criminal. A law should be passed requiring a qualified physician to visit every case of sickness in order to decide whether the case was a contagious one. This physician should be a public official, so as to prevent all free advertising." Discussion of the formal topic, the public's duty to the medical profession, brought out statements that physicians were not in touch with the public because the public were kept too much in ignorance of the profession's work; lectures by practising physicians should be encouraged, not frowned on as advertising; there was too much "professional etiquette." The world should be kept informed of the progress of science. Dr. A. Jacobi was one sponsor for these views.

The other speakers were Drs. F. R. Sturgis and Robert F. Weir.

PHILADELPHIA.

Orator for Academy of Surgery.—Dr. Joseph M. Spellisy has been elected Orator of the Academy of Surgery for 1902.

Physical Culture in Public Schools.—Governor Stone has approved the measure enacted by the Legislature providing that systematic and regular instruction in physical culture be given in the elementary schools. This act is believed by many to be unconstitutional, but will probably soon be put in force in this city.

Dermatological Society Formed.—The Duhring Dermatological Society has lately been formed with Dr. H. W. Stelwagon as chairman. Monthly meetings are held at various hospitals for the purpose of discussing cases.

Endocarditis from Typhoid Fever.—Dr. J. A. Scott exhibited a patient at the Section on Medicine of the College of Physicians, April 8th. The young man had an undoubted attack of typhoid fever of a rather mild variety. During the attack, pain was noticed in the left chest, and a cardiac murmur was heard. This mur-

mur still persists and is made louder by exertion on the part of the patient. The diagnosis of endocarditis was made from the cardiac symptoms, leucocytosis (as high as 15,000 at one time and over 14,000 at other examinations), the pain, and the murmur which is still increasing. Drs. Tyson and Hare inclined to the opinion that the murmur was due to relative insufficiency instead of endocarditis. Drs. Eshner and Packard thought that the symptoms pointed to endocarditis.

CHICAGO.

Transfer of Dr. Holt.—Dr. John Milton Holt, Assistant Surgeon, U. S. M. H. S., in charge of the Marine Hospital of Cairo, Illinois, has been transferred to Chicago. He will be succeeded by Past-Assistant Surgeon James H. Oakley, who has been stationed at Queenstown, Ireland.

Definition, Pathology and Symptomatology of Epilepsy.—In a symposium on epilepsy at a meeting of the Chicago Medical and Neurological Societies, held April 3d, Dr. Elbert Wing discussed this subject. All writers practically accept the conditions of Gowers' definition of epilepsy, and it may be affirmed: (1) That impairment or loss of consciousness is the fundamental phenomenon in a paroxysm of epilepsy. (2) That convulsions of a purposeless type may or may not accompany the disturbance of consciousness. (3) These phenomena must not be due to active brain disease, blood states, reflex irritation or primary failure of heart's action; that is to say, it is possible to distinguish attacks of idiopathic epilepsy from attacks which closely simulate epilepsy, but which occur in connection with other diseases. Paroxysms of minor attacks or petit mal occur in two principal forms, with or without warning. In one there is only momentary arrest of consciousness with or without interruption of consciousness. The other form constitutes the varied phenomena of double consciousness, and between these extremes all variations occur. Reference to two types may suffice. Some believe no attack is free from some motor disturbance, *i.e.*, mimetic movements of facial muscles. Others claim that attacks of profuse sweating and unconsciousness are the only symptoms. The writer has one such case under observation. The relation of migraine to epilepsy is so often mentioned that it demands a passing reference. These diseases have in common neurotic heredity, periodicity, early beginning, and at times the same exciting causes. Many sufferers with migraine have become epileptics and both diseases may occur in the same person. In some cases of so-called ophthalmic migraine the symptoms closely resemble the aurae of epilepsy. Some such cases have been cured by bromides. Kraft-Ebing's statement is generally accepted, namely: "I do not know a single case in which simple migraine could be clinically related to epilepsy."

Diagnosis and Variations of Epilepsy.—This phase of the subject was discussed by Dr. Harold N. Moyer. Epilepsy is easily identified when the convulsive attacks are typical. Unfortunately, the family physician often and the consultant almost invariably rely upon the descriptions of lay people for the sequence of events in the seizure. Epilepsy is a symptom-complex, but unlike chorea and other symptomatic disorders of the nervous system, any of the features which make up the attack may be absent in a particular case. The definition of epilepsy by Donath seems to be as satisfactory as any so far proposed. It is this: "An abnormal excitement of the cerebral cortex which increases suddenly, is periodical in its manifestations, has a typical course and disappears rapidly. Whether the attack occurs without unconsciousness and amnesia, depends upon the strength and extent of the irritation." The ordinary classifications of grand mal and petit mal are provisional only as they relate to the severity of the convulsions, the one shading into the other, but such a definition is useful. A lapse of consciousness is the most constant feature in an epileptic seizure, but it may be absent even in cases which are characterized by convulsions, though the latter is very rare. In petit mal the loss of consciousness is very slight, or may not occur at all. Jacksonian epilepsy is by no means clearly demarcated from other forms, but it is so commonly understood to mean those attacks which begin in a limited area of the cortex and extend by continuity. Sometimes the convulsions become general with a loss of consciousness, but more frequently they are only partial. The greatest difficulty in the diagnosis of epilepsy is the so-called equivalents, which are simply psychical states sometimes marked by automatic acts, alteration in the emotion or dream states. They may consist in alterations in the sensory perceptions, the so-called aurae. A very unfortunate combination of words is that known as hystero-epilepsy. These cases are hysteria and not epilepsy. They are distinguished from true epileptic attacks by the absence of an initial cry, the movements are at least coordinate if they do not have a purposive character, the tongue is not bitten, the patients do not injure themselves. The duration of each convulsion is several hours with frequent remissions. Consciousness is generally preserved. Emphasis was laid upon the importance of the early recognition of epilepsy.

Mental and Allied States.—Dr. Sanger Brown said that suddenness and violence of phenomena in epilepsy are suggestive of chemical reaction. Therapeutic measures founded upon the theory that the disease is due to an excess or diminution of this or that organic substance in the economy have been disappointing. Heredity may be divided into similar and dissimilar. Similar heredity implies the existence of epilepsy in ascendents, while dissimilar heredity refers to such ancestral diseases as insanity and imbecility. That the disease is due largely to an inherited defect of the nerve ele-

ments, rendering them unduly stable, and conformably to the fact that a majority of all hereditary cases begin during the same period, would be expected when the instability of the nervous system during childhood, youth and adolescence is remembered. The author's experience does not either confirm or contradict the statement that cases of hereditary epilepsy are more amenable to treatment than those devoid of that feature.

The psychic or mental manifestations were divided into those momentarily preceding or terminating in other phenomena, or those extending over a period ranging from a few minutes to a few days prior to the seizure or seizures, those which alone comprise the individual attack and those which are the result of the fits either momentarily or remotely, and finally, a class of cases in which the mental disease or disorder is of such a nature that it might be more properly regarded as an association with, rather than an expression of, epilepsy. Of the first class, the most common are those which momentarily precede the fit, and fairly constitute the mental or psychic aura. To mention these in the order of their frequency, those cases come first in which a familiar environment seems strange, and next those in which the surroundings seem a repetition or at least peculiarly familiar. There is a vivid mental perception of detail, sometimes analogous to the visual impression made by a lightning flash in dense darkness. Vague fear, but perhaps intense; a depressing sense of confusion; a consciousness of absurd or trivial mental contents; anger; revenge; joy amounting sometimes almost to a mental or psychic orgasm; a vivid recollection, sometimes quite elaborate. Those changes which precede the seizure for a variable period are properly regarded as premonitions. They commonly consist of marked irritability, depression, violent explosions of temper, indecency, untruthfulness, or a sense of mental exhilaration and joyousness rapidly progressing to maniacal confusion and frenzy. Doubtless, transitory frenzy might constitute a valid defense for homicide. Indeed, a defense of this kind would be very strong if the defendant were known to suffer from epilepsy, whether the frenzy had been previously known to be intimately related to the fits in point of time or not.

The Treatment of Epilepsy.—Dr. Daniel R. Brower spoke on this subject. The prophylaxis of epilepsy demands much more attention than it ordinarily receives. The prophylaxis of post-traumatic epilepsy requires the prompt and judicious treatment of every head injury. The speaker discussed the prevention of individual seizures, treatment during an attack, and the care and treatment between the seizures. Hydrotherapy is an important aid to treatment. A vigorously active skin means a more perfect elimination of toxins. A tepid bath with an abundance of soap is ordered twice a week, temperature 125° F., and a cold douche of an average temperature of 75 daily, to be followed by vigorous friction. Cerebral galvanization is of value. Large electrodes should be used, and a current strength of from one to three milliamperes, and daily if possible. Two steps in this cerebral galvanization are, first, the current is passed longitudinally, the positive over the forehead, and the negative over the nucha; and, second, from temple to temple; the séance should last about ten minutes. Some form of gymnastics should be ordered for the great majority of cases. The bromides still hold the first rank in the treatment. They must be used with proper precautions, and bromism avoided. They must be used for a long time. No case can be called cured until the seizures have been stopped for at least five years. Their curvative action requires the production of their full physiological action, but not their toxic. He rarely exceeds one dram (4.00) a day, and is of the opinion that one dram and a half (6.00) should not be exceeded in any case. A serious objection on the part of some patients to the use of the bromides is the acne which it produces, a result that depends less upon the dose than upon the idiosyncrasy of the patient. Taking the mixture with a very large amount of alkalinized water diminishes the amount of it, as does also the addition of liquor sodii arsenatis in from three to five minims (0.20 to 0.30) to each dose. The arsenic by its alterative and tonic qualities aids the cure. In ordinary cases the iodide of sodium should be given in doses of five grains (0.30) three times a day in the bromide mixture. In the syphilitic cases it should be given in the largest dose that is possible. When the moderate doses of the bromides fail to stop the seizures, he advises a dose of grs. x to grs. xx of chloral at bedtime, often with benefit. Acetanilid is synergistic to the bromides, and when administered in grs. 2 to 5, three times a day, will sometimes be of service. The opium-bromide treatment has not been satisfactory in his hands. Glonoin and the nitrite of sodium are valuable remedies against the petit mal attacks, when given in conjunction with the bromides. The best intestinal antiseptics are salol, salicylate of bismuth and guaiacol carbonate. As to tonics, strychnine, arsenic, the hypophosphites, phosphoric acid and iron are at all times of service. He gives iron, perferably the bromide, in gr. ½ dose, three times a day, whenever the hemoglobinometer indicates it, and then it is of great value. The results that have followed cervical sympathectomy, oophorectomy, ligating the vertebral arteries, and the carotid arteries, have not been such as to justify advising them. If epilepsy is essentially a disease of the cell bodies, of cortical neurons, and a proliferation of the neuroglia, then all such operations are unscientific.

The colony system is the highest ideal for the treatment of these unfortunates. The proof of this is overwhelming in results obtained both at home and abroad.

GENERAL

St. Louis Medical Society.—The subject of Urinary Fistula was discussed at the last regular meeting of this society, held Saturday, April 6th. Dr. Bryson read the paper; Drs. J. G. Holland and C. O. C. Max were recommended to fellowship.

Transportation to the American Medical Association.—The Western Passenger Association has granted reduced rates throughout its territory to members attending the American Medical Association. From all points more than 200 miles from St. Paul the price will be that of a single fare plus $2.00. All communications will be answered by the Medical News and by addressing H. C. Johnson, M.D., Chairman of Committee on Transportation. Readers of the Medical News who desire to know the rates, routes, etc., will please communicate with editor who has full information.

Medical Society of the State of North Carolina.—This society will meet in Durham, May 21st, 22d and 23d, under the Presidency of Dr. Julian M. Baker of Tarboro. The oration will be delivered by Dr. Earle Grady of Tryon; the essayist is Dr. R. S. Primrose of Newbern. The annual debate will be opened by Dr. D. A. Stanton of High Point. Dr. A. G. Carr of Durham is Chairman of the Committee of Arrangements.

Study of Epilepsy.—The first annual meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics will be held in Washington, D. C., May 14 and 15, 1901. Many papers of value from European and American students and full reports of the progress that is being made in the care and treatment of epileptics in this country, are promised for this evening. The President of the Association is Hon. Wm. P. Letchworth, LL.D., Portage, N. Y.; First Vice-President, Frederick Peterson, M.D., New York City; Secretary, Wm. P. Spratling, M.D., Craig Colony, Sonyea, N. Y. Drs. Peterson and Spratling, upon request, will give further information of the coming meeting.

New Orleans Polyclinic.—On account of various requests the session of the Polyclinic will be continued to May 31st, instead of May 11th, as announced in catalogue.

Gift to Liverpool School of Topical Medicine.—According to *Science*, the father and uncle of Dr. Walter Myers, whose death from yellow fever was announced some time past in the Medical News, have given $7,500 to the Liverpool School for the purposes of original investigation.

Women Doctors in South Carolina.—For the first time in the history of the medical profession of this State two young women have been graduated as practising physicians from the Medical College of South Carolina. At the commencement exercises, April 3d, diplomas were awarded to Miss Emilie M. Viett and Miss Rosa Hirschman of Charleston. They are the first graduates of the institution.

Suspected Plague Case at Ann Arbor.—The case reported to be bubonic plague, which was discovered at the University of Michigan, is under treatment in the college pesthouse, which is isolated, and the authorities declare that there is no possibility of a spread of the disease. The patient is a student in the medical department, and became infected, it is alleged, while studying plague germs in bacteriological work. The case was at first diagnosed as pleurisy, but later developments led to the summoning of Dr. Novy, who says:

"I have made cultures from the young man's blood. I shall inoculate guinea-pigs and can tell from the results whether it is really 'black death.' One thing makes the case look favorable. A burning fever accompanies bubonic plague. The young man has very little fever."

Women Medical Students.—Dean Victor C. Vaughan of the University of Michigan Medical School has set his seal of disapproval on the work of women in the department of medicine. The dean's remarks were made before the members of his class in hygiene: "Woman's Lack of Originality" formed the theme for the professor's discussion. "Once a year," said Dr. Vaughan, "I like to tell my opinion of women engaged in the study of medicine. In text-book work generally a woman student will make a better recitation than a man, but when it comes to relying on personal judgment she nearly always fails in efficiency. There are brilliant exceptions to the rule, but when a young woman is thrown on her own resources in a laboratory she fails to come up to the standard set by the students of the opposite sex."

Physician Not Bound to Answer Calls.—The Supreme Court of Indiana decided April 4th that a licensed practising physician is not legally bound to attend any patient for whom he is called, although he may have served as family physician for the sick person's family in the past, and he is not liable for damages for refusing to answer calls. The case came up from Montgomery County, where Dr. George Weddingfield refused to attend the wife of George D. Hurley, although called on three times, the last time by a preacher, who offered to pay the fees in advance. It was charged that the woman's death was due to the lack of a physician's aid, and the doctor was sued for $10,000 damages.

Christian Scientists in Minnesota.—A decision of the Supreme Court of Minnesota maintains that Christian Science healers are not practising medicine while engaged in their calling and hence are not amenable to the medical regulations.

To Aid the Older Physician.—In the recent annual report of the Connecticut State Board

of Health the suggestion is made that some modification of the Registration Act of the State be made so as not to exclude old and skilled physicians not technically up in the minute points required in the examinations. On this matter the report says: "If present conditions continue the profession in this State will be almost a close corporation, limited to those who join it while they are fresh from their college work, and their memory is still retentive of chemical formulæ and of minute points in anatomy and physiology."

Connecticut Death-Rate.—The death-rate for the State during the year 1900 was 17.9 per 1,000. In ten years, notwithstanding the fuller returns of deaths, the rate has fallen from 19.2 per 1,000 to 17.9 per 1,000. The divorce laws appear to be better enforced in the State, as, in spite of increase in population, divorces have fallen from 477 to 431 during ten years. On the other hand, births, in spite of fuller returns and increase of population, have been almost stationary for eight years, there being 20,395 in 1900, as compared with 20,296 in 1893.

Connecticut Sanitary Science.—The annual report of the State Board of Health, one of the most carefully prepared of the State reports, was published this week. After noting the improvement in sanitary administration in the State during the last few years, the report calls attention to the rapid increase in pneumonia. That disease has now outstripped consumption in mortality, and, out of 16,263 deaths from all causes in Connecticut during 1900, there were 1,631 victims of pneumonia, as compared with 1,476 from consumption and 1,341 from heart disease. During the decade from 1890 to 1899, inclusive, the average annual mortality from pneumonia has been 1,296, as compared with an annual average mortality of 776 during the thirteen years previous. The disease is, the report says, in close accord with the development of late years of influenza and la grippe. The tables indicate that consumption is slowly dying out.

Typhoid in Connecticut.—Some remarkable figures are given in the last annual report to show the large mortality from typhoid fever in private practice as compared with hospital treatment in 1900. Returns from six hospitals with 693 typhoid-fever patients show a mortality of but 6.8 per cent., while 1,163 cases in the whole State showed a mortality of 20 per cent. An official report of the Forestville epidemic of typhoid fever resulting in 50 cases and 7 deaths is given, showing clearly that the disease originated from river water contaminated by human excreta from a factory, the water being pumped into the regular Forestville supply owing to a break of a pipe where it crossed the stream.

Appointments by the State Health Commissioner.—Dr. Daniel Lewis, State Commissioner of Health, April 8th announced the following reappointments of employees in the State Health Department: Dr. F. C. Curtis of Albany, medical expert; F. D. Beagle of Oneida county, registrar of vital statistics.

Hospitals Benefited.—By the will of the widow of Senator John McPherson of New Jersey, on the death of her daughter, $10,000 is to be given to the Emergency Hospital in Washington and $50,000 to Christ Hospital, Jersey City.

Christian Science Invading Germany.—The *Deutsche Evangelische Kirchen Zeitung*, a leading Protestant organ in Germany, bitterly complains that of late "the so-called Christian Science has been imported from America, and is now being spread by Americans residing in Germany, particularly in Berlin." The paper declares that the movement is making rapid progress among the higher, and even the highest, classes, although exclusively among ladies thus far. It characterizes the belief of Christian Scientists as "superstition," and their practices as "methods for wringing money from the unwary." The article, which is now making the rounds of the press, has created a sensation.

Insanity Not on the Increase.—The State Board of Insanity in Massachusetts agrees with that of Indiana in the belief that much of the apparent disproportionate increase in the number of insane in public institutions is due to the marked and growing tendency to commit all classes of the insane to institutions, especially in the case of old people, of the feeble-minded, and of criminals. It is an increase of registered, but not of occurring, insanity, the rate of increase in the latter being asserted to be much less than the apparent increase of the insane. Nevertheless, the annual increase in the number of insane in Massachusetts is about 300, and the provisions for their accommodation are inadequate. Of the 7,417 patients in public hospitals and asylums on October 1st last, something over 13 per cent. were sleeping on cot beds made up each night in the corridors and the day rooms. This, of course, was detrimental to the health of the patients. In addition to the annual increase, the State is to assume the care, after 1903, of all the insane in city and town almshouses. These now number about 900. In Connecticut, too, the number of insane is in excess of the public accommodations. There are 2,135 patients in the asylum at Middletown, which is 500 more than there is room for, and the number is being added to at the rate of 100 a year. The building is crowded with humanity like cattle in a pen, a legislative committee reports, and in a garret they found 100 men packed in where there was room for but twenty. The presentation of these facts hastened the appropriation by the Legislature of $165,000 to increase the accommodations.

Rudolf Virchow Fund.—The American medical profession is asked to notice that on October 13, 1901, Dr. Rudolf Virchow will be

eighty years old. When he completed his seventieth year a fund was started in his honor to enable the great master to facilitate scientific research by establishing scholarships, and by encouraging special medical and biological studies. Contributions to that "Rudolf Virchow Fund" were furnished by those in all countries interested in progressive medicine, as a homage to the man whose name is always certain to arouse admiration and enthusiasm. In Berlin a large committee, containing amongst others the names of A. Bastian, Von Coler, A. Eulenburg, B. Fraenkel, O. Israel, Fr. Koenig, C. Posner and W. Waldeyer, has been formed to call for contributions which are to be added to the original "Rudolf Virchow Fund" so as to increase its efficiency. The Committee expresses the opinion that in no better way, and in none more agreeable to the great leader of modern medicine, can his eightieth birthday be celebrated, and asks for the sympathy and cooperation of all those engaged in the study and practice of scientific medicine all over the globe. The undersigned have formed a subcommittee for the purpose of making the American profession acquainted with the intentions of the Berlin Committee, and urge their colleagues to participate in honoring the very man who has done more, these fifty years, than any other to make medicine a science and international. Subscriptions should be sent to the secretary, who will receipt therefor.

Charles A. L. Reed, President of the American Medical Association.

Henry P. Bowditch, President of the Congress of American Physicians and Surgeons.

William K. Welch, Johns Hopkins University.

Robert F. Weir, President of the New York Academy of Medicine.

A. Jacobi, 110 West 34th Street, New York, Secretary.

New Haven's Typhoid.—It was said that on April 6th there had been 125 cases of typhoid fever in this city and that the disease has reached epidemic proportions. Never in the history of the Board of Health of New Haven have there been so many cases at one time here. The record prior to this was made in 1897, when there were sixty-three cases, many of them proving fatal. Two weeks ago the city was practically free from the disease. In the western part of the city there started half a dozen cases at once and since then the new cases have been reported at the rate of six a day. A special typhoid ward was fitted up at the New Haven Hospital last night with a corps of three nurses and one orderly. Sixteen patients have already been taken there for treatment. One of them is N. N. Berg, a student of Yale. Another Yale student who is ill is J. Frank Flynn, but he has been taken to his home in Meriden. There are two Yale men in the Yale infirmary with the disease. The health officials have said that they have traced the origin of the disease to Dawson Lake, a feeder to the New Haven Water Company which supplies the city. Near a brook leading into Dawson Lake resided a family that last winter had three cases of typhoid fever. Typhoid organisms have found their way into the brook and went to the lake and have since been running through the water pipes of New Haven. Later reports show that there have been officially reported 186 cases altogether. There have been thus far no deaths. An expert from Lehigh University, who has examined the cases, says that they are of a malarial character, but both the local and State health officers pronounce them genuine typhoid.

Obituary.—John H. Grove, M.D., LL.D., a well-known surgeon of Philadelphia, who was brevetted Lieutenant Colonel for distinguished services in Union military hospitals during the Civil War, died last week. For many years he was medical director of St. Agnes' and St. Mary's Hospitals in Philadelphia. In 1899 he presented a memorial chapel to the Presbyterian Church in Marietta, Pa. He was born in 1825 in Maytown, Pa. He was a fellow of the College of Physicinas, a member of the Society of Medical Surgeons and a Mason of high degree.

Dr. Thomas A. Hill, formerly of Chicago, but since 1894 a resident of New York, died of apoplexy April 5th in his eighty-fourth year, at Danville, Ill.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 1, 1901.

THE KING'S PHYSICIANS, SURGEONS, APOTHECARIES AND DENTISTS—THE KING'S HEALTH NOT AS GOOD AS IT MIGHT BE—THE COURT DOCTORS AND THEIR CHARACTERISTICS—PHYSICIANS ORDINARY AND EXTRAORDINARY.

The *London Gazette*, which is the official organ of the Court, in its issue of March 29th contains the names of the physicians, surgeons, apothecaries, dentists, etc., who have been chosen to minister medically to the person of King Edward VII. The list comprises thirty-three names, so that, if it be true there is safety in a multitude of counselors, it ought to be many years before our Gracious Sovereign adds the title of "Late" to the many and manifold designations in which he already rejoices. Your readers doubtless remember the story of the courtier who, in speaking to Louis XVI., referred to *"Sa Majesté le feu Roi d'Espagne,"* and how the *Grand Monarque* was shocked at the expression till it was explained to him that *"c'est un titre qu'ils prennent."* Were it not that the text quoted above might be interpreted as meaning that the safety was for the counselors rather than for the counseled, it might be thought that the complaint most

likely to create a vacancy in the British throne was a "complication of doctors"—a development of pathological science of which the credit belongs to an American jury.

But if Edward VII. could probably dispense with many of his doctors, it is pretty certain that he will need a good deal of doctoring. His life is, from the insurance point of view, by no means a good one. The real reason why his broken kneepan was not wired two or three years ago was simply that the surgeons thought the operation too risky in view of the constitutional condition of the patient. He is much inclined to obesity, and though he has suffered much on this score from more than one physician, the royal form is still such as might make applicable to Edward VII. Beau Brummel's unkind remark spoken *at* George IV., "Who's your fat friend?" Then his water is not, as Falstaff's doctor said of his illustrious patient, "in itself a good water," for it contains, or at any rate did recently contain, albumen and sugar. Withal His Majesty, like his mother, is a great eater, and nowadays takes little exercise.

It would be tedious to inflict on you the full list of the new Court doctors. The physicians in ordinary are Sir William Broadbent, Sir James Reid and Sir Francis Laking. The only one of these who counts for anything in the eyes of the profession is Sir William Broadbent who has done some good work, notably in the domain of heart disease. He is an eminently sensible man, of much shrewdness but little brilliancy. He may be described as a glorified family physician. He steadfastly labors in his vocation in the spirit of Iago's advice to Roderigo "Put money in thy purse." This he does in all honesty and without the aid of questionable methods, the impolicy of which he is astute enough to perceive. He has an immense *clientèle* among financial leaders in Israel, and was at one time the trusted adviser of the Prime Minister. Some disagreement with Lady Salisbury in her last illness, however, lost him the favor of her lord, and his political influence which was supposed to be considerable suffered obscuration. It should be explained that the political influence of a physician in high places here is exerted mainly in procuring titular distinctions for his friends and the patronage of his exalted patients for schemes and institutions in which he is interested. It is only fair to add that Sir William is a man of marked independence of character with a high sense of professional dignity.

Of Sir James Reid enough was said in my last letter. His appointment is doubtless nothing more than a graceful recognition of his long and faithful guardianship of the late Queen. Sir Francis Laking has for many years been Apothecary, that is family doctor, to the royal household. His connection with the Court has hitherto been rather by way of the backstairs. But with the new King he is a *persona grata*, and his professional respectability is beyond challenge.

In addition to the Physicians in Ordinary, there are Physicians Extraordinary. To this nominal dignity have been appointed Sir Joseph Fayrer, Sir Richard Douglas Powell, Sir Edward H. Sieveking, Sir Felix Semon, and Dr. John Lowe. Sir Joseph is well over eighty and lives in retirement. He won a great name for himself in India, and during the famous siege of Delhi in the Mutiny, his house was one of the chief strongholds of the garrison. He accompanied the King, then Prince of Wales, in his progress through India. For many years he was Medical Adviser to the Indian Office here, and he has beguiled the tedium of an enforced leisure by literary production, the most interesting of his writings being an autobiography which, as far as it relates to his Indian career, is a historical document of considerable importance. Sir R. Douglas Powell is in appearance and manner and, it may be added, in his somewhat unctuous rectitude, of professional conduct the very type of the dignified physician. To him, it is said, was due the extraordinarily periphrastic phraseology in the bulletins about the late Queen, which were classic examples of the use of language to conceal thought. Sir Edward Sieveking has been off the active list for some years. Except titularly, he has never had anything to do with the Court. He had a great disappointment in his professional life, for when the Prince of Wales was struck down by typhoid fever in 1871, Sieveking was sent for in the first instance to assist Jenner. He was out of the way, however, and the late Sir William Gull was invited to go as a temporary substitute. But Gull once at the bedside of the royal sufferer refused to leave it. Like Marshal Macmahon in the Sedan, he said *"J'y suis, j'y reste."* Sir Felix Semon is a German Jew with the vertebral flexibility and insinuative perseverance which are the badge of his tribe. When he first came to this country, he attached himself to Morell MacKenzie. As soon as he could afford to be independent he prudently made friends to himself of a more respectable kind of professional Mammon, and he has had his reward. He advised Gladstone when the great orator's voice was beginning to fail, but his counsel was not sought in the Grand Old Man's last illness. Sir Felix Semon is a man of real talent, but he does not need to pray with the Scotch minister of the story that "God may give him a guid conceit o' himsel." Dr. John Lowe is a general practitioner of Sandringham in Norfolk where the King lives the life of an English country gentleman, and was in attendance when His Majesty had typhoid fever.

Appearance of American Medicine.—Dr. George M. Gould's new enterprise, *American Medicine*, has just appeared. We wish it success.

TREATMENT OF CANCER—PUERPERAL SEPTICEMIA—LARGE-INTESTINE HERNIAS—CANCER OF THE RECTUM—STERILIZATION OF COCAINE SOLUTIONS.

Launois, at the Société de Chirurgie de Paris, February 20, 1901, discoursing on the treatment of cancer, reported the very promising results following subcutaneous injections of a soluble salt of quinine after the method of Jaboulay, in an inoperable case of cancer of the uterus. The symptoms were accentuated paresis of the lower extremities with considerable pain and functional derangements. Under the influence of subcutaneous injections of chlorohydrate of quinine, repeatedly exhibited, these phenomena disappeared and the ulceration of the neoplasm itself ameliorated to a marked degree. Tuffier, in the discussion, said that he has found the cacodylate of soda equally as efficient as the quinine salt recommended by Jaboulay. A large mammary cancer with extensive ulcerations had materially changed for the better under its exhibition hypodermatically, frequently repeated. Bazy emphasized the peculiarity of cancer to undergo occasional arrest or amelioration independently of all treatment. He had removed a large cancer of the breast associated with paraplegia and gibbosity. Both disappeared spontaneously after the operation. Felizet suggested the interest inherent in an attempt to prevent recurrence by resorting to these injections during the after-treatment following an operation. If the method of Jaboulay and Launois is efficacious, this would probably also avail greatly. Berger said he has frequently used the serum of Wlaiev and noted occasional marked improvement in the symptoms, especially the functional and pain signs, but as to the growth itself as a pathological process he has unfortunately not seen any change. In fact he felt that we are not on the point of finding any real cure for cancer. Nimier said he had lately seen not the slightest improvement in a lingual cancer or in its metastatic deposits in the glands of the neck, following the use of Wlaiev's serum.

Rochard, at the meeting, February 27, 1901, discussed surgical intervention in puerperal septicemia and reported five such cases with five deaths, following the operation. In one case there were multiple purulent foci which he evacuated and otherwise cleaned out the pelvis, but the patient died right after the operation. In three of the remaining cases abdominal hysterectomy was done; in the last vaginal hysterectomy was done. He feels that death was not due to surgical treatment, but to the delay in its application. The indication is removal of the uterus as the main focus, but such removal must be done very early. As to the avenue for the removal, he felt that the abdominal route is the better, because it gives a wider view of the lesions. The friability of the infected postpartum uterus constitutes a serious obstacle to its extirpation by the vagina, practically a contra-indication.

Schwartz in reviewing the clinical features of hernia of the large intestine named two varieties; one in which reduction was easy because the sliding condition of the bowel and its partial peritoneal covering was still maintained, and the other in which adhesions prevented liberation and reduction. The technic of dealing operatively with the former has already been enunciated by him and is comparatively simple. In the latter in a recent example he resected *in toto* all the adherent bowel, but that did not prevent the patient from dying.

Berger stated that four or five years ago with the aid of Quénu he removed the whole of the rectum and part of the sigmoid colon by the perineo-abdominal route for cancer. Within a few days he had again seen the patient and found him in a most satisfactory condition. No sign of recurrence and the artificial anus operating well. Although the lesion was shown to be chronic inflammatory and not cancerous in character, nevertheless the good condition of the patient was attributable to the operation. By the perineal route in an old woman he has recently removed fourteen centimeters of the rectum which covered twelve centimeters of its extent. As a preliminary step he made an artificial anus by the intramuscular method and found that, after a few days of trouble, owing to the contraction of the muscles checking the outflow of feces, it made an admirable anus. After freeing the bowel he shortened the technic by placing an elastic ligature about the bowel which came away, leaving the stump healthy and in apposition with the external wound, after about twelve days. As another preliminary to this operation he commends the taking away of the coccyx because it exposes the perirectal fat and leads directly to the levatores and their associated planes of fascia, thus facilitating easy enucleation of the bowel from its bed.

Reclus, in discussing the various means of rendering cocaine solutions sterile, said that the simplest is that of Hérissé, who, in 1898, found that the rotatory power of cocaine is not lost by boiling. The speaker's own experience was that the anesthetic qualities of the drug are also not affected by boiling any more than by heating in the autoclave to 115° to 120° C. He had recently used a solution three months old which had been raised to 120° C. in the autoclave and found its anesthetic powers perfect.

Fresh Air Home for Nurses.—Mrs. Walter B. James has recently purchased a place at Far Rockaway for a fresh-air home for trained nurses.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting, Held March 14, 1901.

William L. Stowell, M.D., Chairman.

Congenital Heart Disease.—Dr. A. Bassler presented a patient suffering from an interesting form of congenital heart affection. The patient is a girl of about six years of age who has constantly had some symptoms pointing to the existence of a heart lesion. Loud murmurs can be heard all over the chest and in the back at the angle of the scapula. A heart beat can be felt on both sides of the chest. While the heart has labored a good deal, there has never been much cyanosis and the child is in reasonably good general health. The lesion seemed to be one of pulmonary stenosis.

Dr. C. G. Kerley said that it is an extremely difficult matter to make an exact localizing diagnosis of a congenital heart lesion. There are many possibilities in the matter of malformation and too little is known about the physical signs that these various anomalous conditions produce to enable the making of a definite diagnosis. The symptoms must be met as they arise, as far as is possible, and the best diagnosis is one that does not assume too exact knowledge of the actual condition present.

Not Uncomplicated Pulmonary Stenosis.—Dr. Libman said that the dulness above the region of normal heart dulness in the first and second interspace in this case seemed to point to the existence of a patent ductus arteriosus. There is no accentuation of the second sound over the pulmonary valves. There seems good reason then to think that the case is not one of uncomplicated pulmonary stenosis. There is another reason for thinking that the case is not merely pulmonary stenosis. This is the presence of a secondary area of pulsation on the right side of the child's chest. This rather than the pulsation on the left side seems to be the true apex beat.

Dr. J. Finley Bell of East Hampton read a paper on Interesting Experiences in an Epidemic of Typhoid Fever, Fetal and Infantile Typhoid and Scarlatina Complicating Typhoid Fever and Vice Versa. This paper will appear in a future issue of the Medical News.

Pathology of Typhoid Fever.—Dr. Martha Wollenstein read a paper on the recent advances in the bacteriology and pathology of typhoid fever. Aberth and Koch described bacilli which occurred in the stools of typhoid patients. Gaffky, however, was the first to have them grow in pure culture. Typhoid bacilli may remain latent in the system for many years and yet retain all their virulence. They have recently been discovered in pure culture in the pus of osteomyelitis, occurring in patients who had had typhoid fever many years before. The best explanation of their presence and their causative action in the osteomyelitis has been recently given as follows. Somehow the typhoid bacilli found their way to the bone marrow. Deposited there they remained absolutely inactive, although living so long as the individual retains the acquired immunity to typhoid fever, which is the result of the previous attack. After the immunity has run out, either as the result of some injury lowering tissue vitality, or even spontaneously, the typhoid bacilli regain their virulence and osteomyelitis is developed.

Life Outside the Body.—Typhoid bacilli readily take up a saprophytic existence. They live most frequently in water, may exist there for several weeks and usually multiply very plentifully. A favorite culture medium for the bacillus is milk. Hence the number of epidemics that take place through this medium. Milk may be infected by hands that have come in contact with typhoid fever discharges, or by being placed in vessels washed with infected water. Other sources of infection are not wanting. Typhoid bacilli cling to particles of dust and may settle on milk, or they may be carried to it on the feet or wings of flies. Dr L. Emmett Holt has shown that they may exist in ice cream.

Other Modes of Contagion.—Typhoid fever may be carried in the air but not for long distances. In a badly-ventilated ward it may travel from bed to bed, even when great care is exercised. As a general rule, however, typhoid bacilli resist drying very poorly and are always killed by complete drying. This preserves the air from serious contamination. Typhoid fever has been conveyed through the rectum by means of enema tubes. Clothing worn by typhoid-fever patients has been known to convey the disease. Monti and others say that typhoid fever may be conveyed by a sick nursing mother. It is certain that the bacillus of typhoid fever can pass through the placenta from mother to child. Twenty-five per cent. of all typhoid patients' urine contains typhoid bacilli and this excretion requires as careful disinfection as the stools. Typhoid bacilli have been found in the sputum. The bacillus has been cultivated from the blood taken from rose spots. The bacilli are found very rarely in throat secretions. They occur very often, however, in the bone marrow. Quincke after carefully investigating this subject found that they occur as often in the bone marrow as in the spleen.

Lesions of Typhoid Fever.—Lesions of the disease are usually in the gastro-intestinal tract. It must not be forgotten, however, that typhoid fever may run its course without any lesions in the intestinal tract and with the occurrence of lesions only in the lungs. In these cases it would seem that the infection has been conveyed through the air.

Typhoid Bacilli Pyogenic.—There is no doubt that typhoid bacilli alone may cause the production of pus. They have been found in pure culture in osteomyelitis. In one case the osteomyelitis occurred in the sternum of a child. Typhoid bacilli have been found as the sole cause of an abscess of the kidney. They undoubtedly cause abscesses of the parotid gland. Suppurative meningitis has also been traced to their activity. In certain cases typhoid septicemia sets in. This is usually fatal. The infection that causes septicemia usually comes through the blood. Bacteriological examination is the only diagnostic method by which a typhoid septicemia can be diagnosed from septicemia due to other pyogenic microorganisms.

Special Pathology of Infantile Typhoid.—The basic pathological process in typhoid fever in children is hyperplastic, rather than necrotic. Peyer's patches are enlarged and swollen, rather than necrosed. This distinction between adult and infantile typhoid has been pointed out by both Baginsky and Monti and has been confirmed by other observers. The dictum that the younger the child the less the number and extent of the intestinal lesions of typhoid is one that admits of many exceptions. It is true that characteristically children's intestines suffer much less than do those of adults, but in some cases of weakling children the intestinal lesions are very extensive and deep.

The Blood in Typhoid.—The red blood-cells diminish progressively during the course of typhoid fever until convalescence becomes established. There are certain variations in the blood-count that from time to time seem to indicate the presence of a larger number of red blood-cells than before. The rise in the average number of red blood-cells occurs just after severe diarrhea or febrile sweating. It is evident that the increase of red blood-cells is only apparent and is really due to the presence of less serum in the circulation than before. Severe hemorrhage lessens the number of red blood-cells directly and adds very markedly to the anemia. The number of white cells is lessened, but only relatively to the number of reds. The presence of inflammatory complications causes a leucocytosis. The occurrence of leucocytosis then should arouse suspicion of the development of some complication.

Value of Widal Reaction.—Dr. John Lovett Morse of Boston discussed the value of the Widal reaction with special reference to its usefulness in the typhoid fever of children. There are three factors that are important for the value of Widal's test. These are, first, the dilution at which the agglutination takes place; secondly, the length of time necessary for its production; and thirdly, the completeness of the clumping of the bacilli. Dr. Cabot of Boston uses a dilution of one to ten for the performance of the test and considers that the agglutination, to have a diagnostic value, should take place within half an hour. The Boston City Board of Health employs a dilution of one to twenty, but allows an hour for the complete reaction to take place. Abroad there is a tendency to employ high dilutions and to allow a long time for the completion of the reaction. In this country a tendency in the opposite direction has been noted.

Widal Experience in Boston.—Dr. Witherington of Boston reports on Widal's test in 253 cases which clinically were typhoid fever. In ten, 4 per cent., the characteristic reaction failed to occur. In all of these the later symptoms and the clinical course showed that the disease was typhoid. In addition to mistakes in diagnosis there are certain reasons, now well recognized, for the failure of the Widal test. In a certain number of cases the power to cause agglutination of the bacilli is present in the blood only intermittently. Examinations at certain times therefore will fail for this reason. In other cases the Widal reaction is never present during typhoid fever at all, although the cases are true typhoid and may prove fatal and show the characteristic lesions at autopsy. Widal himself has reported a case in which the reaction was absent and yet typhoid fever bacilli were obtained from the skin. The reason for the absence of the test is not known in certain cases and it constitutes a small, but a real possibility of error that prevents the test from being absolutely diagnostic.

Duration of Agglutination.—In some cases the power to cause agglutination remains in the blood as long as ten years after recovery. In about 70 to 75 per cent. of the cases, however, it disappears under five years. This constitutes another source of error for the Widal test. It would seem that in certain cases, notwithstanding the persistence of the power of agglutination, reinfection may occur. In 365 cases of patients not suffering from typhoid fever and with no history of typhoid fever, Cabot found the Widal reaction once. The source of error from this source, therefore, is probably very small.

Occurrence of Widal.—The Widal reaction is present in over 95 per cent. of all cases of typhoid fever. It is seldom present before the second week of the disease. As to its absolute diagnostic value, it seems as near certain as anything can be, that the case is not typhoid if the Widal reaction is absent, after a reasonable length of time, with a dilution of one to fifty.

Widal Test in Children.—It has usually been presumed that the Widal test is the same for children as for adults. The subject has not been very much discussed, however. Examination of recent statistics shows that the agglutinating power is weaker in children, that it appears earlier in the disease and

persists for a shorter time than in adults. The test is of special value in differentiating gastro-intestinal diseases, running their course with fever. The drop in the reported number of hospital cases of typhoid fever in children in recent years, is undoubtedly due to the more general use of the Widal test. On the other hand the use of the Widal test enables the physician to make a positive diagnosis of typhoid fever in many mild cases in which the presence of the disease was scarcely suspected. The Widal reaction in infants takes place much as in older children, but it is of less diagnostic value. The agglutinative power can pass through the placenta or may pass through the mother's milk. In one case it was transmitted through the milk as long as fifteen years after the occurrence of typhoid fever. The power of the child's blood to reproduce the agglutinative reaction after it has been obtained through the milk is not very persistent, however. It may not last for more than a week. In nursing children then the presence of the Widal reaction has no definite significance as regards the presence of typhoid fever, unless other symptoms are present that clearly point to the existence of the disease in the infant.

Infantile Typhoid Rare.—Dr. W. P. Northrup said that infantile typhoid is not as rare as it is said to be by some people and that the Widal reaction is of importance in deciding as to the presence of the disease. In a case recently under Dr. Northrup's care, nine months old, the patient's father and two brothers were sick with typhoid fever. The mother did not nurse the infant, but the child was allowed to play on its father's bed, where it evidently absorbed from its fingers a large amount of infectious typhoid material. The child's passages became frequent and greenish in color and it suffered for several days from continuous fever. On the sixth day characteristic rose spots developed. The temperature continued at 103° F. for nine days and did not become normal until the twelfth day. When the temperature began to run a normal course, the passages became less frequent and the spleen diminished in size. The blood was carefully examined for plasmodium malariæ, but none were found. The Widal test was tried during the first ten days, with negative results until the twelfth day, when a positive result was obtained. Four days later it was found once more to be positive.

Incidence of Infantile Typhoid.—Dr. Northrup said that very varying opinions are held in different parts of the country as to the occurrence of typhoid fever in infants. While infantile typhoid is very rare in New York, it occurs not infrequently in Chicago. It is evident that only when an epidemic is especially virulent, does the infected material acquire sufficient strength to affect the usually immune infant. Infantile typhoid does occur, however, in New York. It is probable that large amounts of infectious material and multiple exposure are required. It must not be forgotten that malaria may occur with typhoid and that if the plasmodium malariæ is found in the blood, this does not necessarily exclude the presence of typhoid.

Infantile Typhoid in New York.—Dr. David Bovaird said that in New York City infantile typhoid is not as frequent as it is elsewhere. Among the manifold intestinal ills of children, especially during the warm weather, typhoid may be easily passed over. Thinking that this might be one of the causes for the fewness of the reported cases, Dr. Bovaird carefully examined all the children admitted last summer to the seaside home of St. John's Guild. Repeated Widal tests were made, wherever there was the slightest suspicion of the existence of typhoid fever. Although hundreds of children were examined from many different parts of the city, not a single case of typhoid fever was discovered.

Delayed Widal Reaction.—Dr. James J. Walsh said that the delay in the occurrence of the Widal reaction in certain cases is probably significant of failure of the organism to immunify itself against the typhoid virus. It would seem that the problem involving the reasons for the delay in the occurrence of the Widal reaction is simpler in children and may be better studied in them than in adults, because of the possibility of properly regulating their diet in various incidents of their illness and convalescence.

Abnormal Typhoid.—Dr. Libmann said that in seventy cases at Mt. Sinai Hospital routine Widal tests showed the presence of typhoid fever in cases in which typhoid fever was not even thought of, because of the clinical history. In one case a typical pneumonia existed. In others meningitic symptoms were present. One child came to the hospital in coma and was suspected of having tuberculous meningitis, but the Widal reaction showed that the typhoid bacillus was at work. The custom at Mt. Sinai is to use a dilution of one in twenty and wait fifteen minutes for clotting to take place. The typhoid bacillus culture that is used should be grown at a temperature of 30° C., rather than at 37° C. Those grown at a higher temperature are more susceptible of agglutination and are more prone to give false reactions.

Dr. Northrup said that, with the one exception which he has reported, he has never in twenty-five years of hospital or private practice seen a sure case of typhoid in an infant. During these twenty-five years 1,200 children have been constantly farmed out from the Foundling Asylum. They have been brought back suffering from all sorts of diseases, but never with typhoid. At times there have been suspicions of typhoid, but the diseases have turned out to be catarrhal enteritis of some

simple type, or some of the anomalous forms of grip, or central pneumonia.

Leucocytosis in Typhoid.—Dr. Morse in closing the discussion said that diphtherla and typhoid fever may prove fatal from an overwhelming dose of the toxins of the disease. Fulminant infection is an index of special virulence and of the intensification of infective material by passage through susceptible individuals. Wherever there exists a leucocytosis one must be very wary in making the diagnosis of typhoid fever. Careful watch of the leucocyte count enables the doctor to anticipate complications of various kinds and gives a good idea of the prognosis. However infantile typhoid may be in other cities, there is no doubt that it is extremely infrequent in Boston. Out of 700 cases of disease in the Infants' Hospital during the last year only one has been suspected of being typhoid. During the progress of this case the Widal test was frequently made, but it proved negative. Dr. Morse said that the question of the Widal reaction being one of immunity or of infection, had not yet been settled. Whether a delay in the agglutinative reaction meant that the system was not properly immunifying itself against relapse of the disease was not known. Definite statistics on this subject were lacking. There was no doubt, however, that the Widal test would prove useful in diagnosis not only for the recognition of typhoid, but also for the anticipation of certain complications of the disease.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held February 15, 1901.

George R. Elliott, M.D., Chairman.

The subject of the evening's discussion was a symposium on Clubfoot.

Etiology of Congenital Talipes Equino-Varus.—Dr. H. W. Berg read this paper. He devoted a part of his paper to calling attention to views elaborated and published by him in 1881. He said it was a fact that talipes equino-varus was a morphological stage in the normal development of the lower extremity of every human fetus. In early fetal life the leg as a whole rotated outward and this outward rotation was accompanied by an exaggerated valgus and later an equino-varus. This outward rotation reached its maximum as soon as the joints were formed. The thighs were flexed upon the body and the legs partially flexed upon the thighs. The wide border of the thigh and the tibial border of the leg pressed against the abdomen of the fetus, the legs crossing each other. All intra-uterine pressure was thus brought to bear directly upon the outer border of the thigh and leg. As a result the foot was rotated in and extended (equino-varus). This then, was a stage in the normal development of every healthy fetus, and were the extremities to remain in this position all children would be born clubfooted. Nature provided against this by an inward rotation of the extremity carrying the leg away from its position against the abdomen of the fetus. The soles of the feet came to lie against the uterine walls and intra-uterine pressure was exerted directly upon them producing extreme flexion and outward rotation of the foot—thus was antagonized the varus or equino-varus which had hitherto existed. This inward rotation began about the second month, was to a great extent accomplished by the fourth month, but not complete till the fifth or beginning of the sixth month. Now, if this *inward rotation*, this second rotation stage did not occur or was incomplete the child was born more or less clubfooted. The different stages of rotation were illustrated by fetal specimens from the museum of the New York Hospital. Dr. Berg denied that his views were those of Eschricht as some had claimed. He said Eschricht, like himself, had said that talipes equino-varus was a stage in the development of the lower extremities of the human fetus, but Eschricht had not explained how it was produced. There was no embryological data at that time (1851).

Mechanism of the Foot.—Dr. J. E. Kelly dealt with the mechanism of the foot and the advantages to be derived from the anatomical study of the factors and treatment of talipes. He called attention to the erroneous idea which persisted as to the existence of a transverse arch in the foot. He said it was impossible, as it had no internal abutment; it bore a greater resemblance to a "flying buttress" the upper and inner extremity of which was supported by the so-called longitudinal arch. In reality it was a semi-dome which with its fellow foot constituted a dome upon the apex of which the weight of the body rested. He called attention to the benefits obtained by utilizing the stability of the margins of the semi-domes in walking especially in those tending to pes planum and talipes-valgus. He dwelt on the fact that the factors in the third and fourth degrees of talipes equinus, varus and equino-varus had best be divided into hyper extension, adduction, torsion and longitudinal folding with the exception of the last, which results from the simple approximation of the internal and external margins of the foot. Each of these factors is complex and may occur in two or more anatomical sites and in different degrees, thus accounting for the infinite variety of talipes. He reviewed the different factors in detail—action of the muscles and resistance of ligaments and observed as a summary that the factors in hyper-extension, or vertical deformity, are the retraction of the heel, luxation downward and forward of the astragalus and the plantar flexion at Chopart's articulation. Adduction is due to the curvature in the neck of the astragalus, dis-

placement of the scaphoid and the traction exercised by the severed tendons and muscles on the inner aspect of the foot. The torsion is caused by the rotation of the scaphoid on its anteroposterior axis, the traction of the tibialis anticus on the inner margin.

Mode of Section.—The author pointed out that the peculiar facilities of section, resection and dissection were afforded in the two margins of the foot and indicated the positions from which the different structures could be most easily reached. He said that, owing to the direction of fibers of the plantar fascia, it was best to divide it posteriorly near the tubercle of the os calcis, where the flexor dig. brevis, the flexor accessorius and the long plantar ligament might be divided. The division should be obliquely forward and outward parallel to the ext. plantar vessels and nerves. Should the external septum need special section, it could best be approached from the external margin. He advocated the division of tendons close to their insertion. Owing to the slight importance of toes in ordinary locomotion, he suggested dividing the numerous digital tendons close to the metatarso-phalangeal articulation. Owing to his observation on the perfect restoration of ligaments of great mechanical importance, he though it expedient in subluxation of the astragalus to consider as an alternative to resection, the free division of the lateral and posterior ligaments and the replacement of the bones which should under the persistent influence of the modeling pressure and adaptive shortening result in a restoration of the articular functions.

Nerve Affections.—Dr. E. D. Fisher in speaking of the neurological aspect of talipes said, that the only class of talipes interesting to the neurologist was that class originating from lesions of the brain, spinal cord or peripheral nervous system. The two main clauses of talipes of this class were diseases of the motor tracts of the brain and spinal cord. Another form of talipes was that due to infantile spinal paralysis. Certain definite symptoms differentiate true congenital clubfoot from that of cerebral or spinal origin. In the deformity resulting from central nerve disease were found reflex disturbances usually exaggerated reflexes associated with spastic conditions of the muscles, and commonly the Babinski symptom—the extension of the toes on irritation. This latter phenomenon associated with exaggeration of the patellar and knee jerk always pointed to disease of the pyramidal tracts and is present whenever there is disease of the lateral tracts, in cerebral hemiplegia in the later stages; in the secondary changes following myelitis; in lateral and multiple sclerosis. In congenital clubfoot on the contrary there was no central nerve disease, therefore no disturbances of the ordinary physiological actions of the spinal cord and brain, hence no disturbances of the reflexes. In making a differential diagnosis between the congenital type of clubfoot and clubfoot due to infantile spinal paralysis, he said the muscular, electrical reactions determined the diagnosis.

Tendon Transplanting.—Referring to treatment, he said of late years interesting experimental work had been done. In cases of spastic paraplegia, for a long time neurologists were opposed to operation, but now he recommended section of tendons, and putting patients in a condition to walk. He referred to transplantation of tendons to opposite muscles or muscles of opposed functions, such as transplanting a flexor tendon to an extensor muscle or *vice versa*. He referred to a boy with central hemiplegia who could not extend his hand. The extensor tendon was transplanted with the result of giving the boy a useful hand.

Dr. Fisher said that deformity could easily be prevented in the early stages of infantile spinal paralysis by mechanical appliances. In the other class of cases in which there was a progressive condition possibly affecting the lateral or motor tracts, more difficulty arose, but he thought surgical treatment with possibly transplantation of tendons of opposite groups of muscles a justifiable procedure.

Non-Operative Treatment.—Dr. Newton M. Shaffer spoke of the non-operative treatment of clubfoot. He said he was accustomed to divide his clubfoot patients into three classes: Vertical, anteroposterior and transverse. By careful study of each case and by making each instrument an individual prescription to fit the given case he had achieved results which at first appeared impossible. The necessity for operation was getting further and further away. He said in the first class of cases of ordinary clubfoot without much deformity, good results could be accomplished by manipulation massage, electricity or perhaps some form of walking apparatus. The careful carrying out of non-operative treatment in these cases should result in cure in a year's time. In the second class where the deformity is greater, especially in equino-varus resistance is present which may be osseous, or fibrous. Experience here was necessary to determine whether operative or non-operative measures should be adopted. It was difficult to give any positive rule, however, although he was inclined to agree with the late Dr. Sayre and not operate if the lesion could be traced to a cerebral source. The rule had exceptions. In the third class, the resistant, some form of operative procedure was usually indicated. This class fell into the hands of the general surgeon.

Referring to cutting the tendo Achillis he said he did not cut when, in taking hold of the foot, he felt the resistance gradually give way.

While he admired Dr. Berg's theory as to the etiology of talipes, he failed to see in conditions found in a child three of four years old, if there was no pathological condition, why

there was delayed growth of muscle. There must be some degeneration or change in the nerve power to account for the delayed growth. He said there was no wide gulf between those who operated and those who did not, but he urged more study of the mechanical principles of treatment and the looking upon apparatus in the light of prescriptions.

Age as a Factor.—Dr. A. M. Phelps, in speaking of the operative treatment of clubfoot, said that in considering when and why to operate nothing had been said regarding age of patient. If a rigid foot occurred in a child two months of age and that same rigid foot in a child of six years there was a vast difference. In the two-months-old baby the condition could be cured by the mechanical, non-operative treatment; in the older child such a thing was impossible. For that reason he believed all cases should be divided into classes according to age and deformity. In a certain type of talipes in new-born children the human hand was the best instrument and the deformity could be cured by manipulation before the child was nine years old. In other cases, even after four months there was great resistance and operation was required the same as at the age of six years. Operations on the soft parts are all that were indicated up to a certain age and to a certain degree. In a child of four months a subcutaneous tenotomy was all that would be required in the majority of cases, but having once commenced to operate the foot must be straightened at the expense of a more extensive operation. At the age of two or three years instead of applying apparatus for a year or so he advised subcutaneous tenotomy observing the rule to get the foot straight.

Regarding open operation he said frequently surgeons neglected to carry out the necessary after-treatment. He objected to the operations when bone was removed, such as removing the astragalus which caused shortening of the leg; or the removal of a V-shaped portion from the tarsus which shortened the foot. He said he resorted to subcutaneous tenotomy and if this was not sufficient to allow of straightening the foot, he made an open wound and cut whatever resisted. Occasionally he found it necessary to take a "V" out of the os calcis; occasionally the deformity was so great that nothing short of amputation was indicated. He advocated thorough operative measures rather than spending years with mechanical appliances and subcutaneous tenotomies.

Dr. Phelps then presented Dr. Hunthy upon whom he had operated ten years ago. Dr. Hunthy stated that treatment for double talipes equino-varus was begun at the age of sixteen years. He had the tendo Achillis, plantar fascia and tibialis posticus tendon divided four times; had worn various forms of apparatus until he was forty years of age, suffering more or less pain from the treatment. Dr. Phelps operated by the open method. He now could walk well and without fatigue.

Dr. George R. Elliott asked what subjective symptoms Dr. Hunthy had had since the operation. Dr. Hunthy replied none except delayed sensibility which lasted two years. Dr. Elliott asked how Dr. Phelps classified the foot at time of operation. Dr. Phelps said it was a case of talipes equino-varus of the third degree. The foot turned almost backward. Dr. Elliott asked if any noticeable change had occurred in the atrophied muscles since the operation. Dr. Phelps replied he did not think there had been any change since the operation.

Operative Risks.—Dr. A. R. Judson said that there was a risk in operating of impairing the innervation of a part below the incision. He had seen cases which showed an improvement in shape with an increase of disability. It was better to pay more attention to the treatment of congenital clubfoot in the newborn than to wait until the lapse of time had changed it to inveterate resistant relapsed neglected or ill-treated clubfoot. Taken in this way, it was among the easier orthopedic problems. The formative condition, the rapidity of growth and the freedom of the foot from the weight of the body made it almost impossible to avoid a good result if due attention were given. Before the child tried to stand, the deformity might easily, and should be thoroughly, overcorrected by the application of a lever, however constructed, a point of pressure being applied alternately against the varus and the equinus with two points of counterpressure above and below. And when the child began to stand a walking brace was necessary which was still a lever, but so applied that the foot was to be held on the valgus side of the plane dividing varus and valgus so that the patient could stamp his foot straight at every step. Braces should be made of tractable metal to be gradually made straight and later more and more valgus, the foot keeping pace with this movement. The varus could thus be completely and permanently reduced and the equinus could be so far overcome as to be practically entirely absent. The necessity of operating in congenital clubfoot was a confession of failure at some time in the history of the case.

VOL. LXXVIII. NEW YORK, SATURDAY, APRIL 20, 1901. No. 16.

SPECIAL ARTICLE.

AN HISTORICAL SKETCH OF THE DEPARTMENT OF MEDICINE AND SURGERY OF THE UNIVERSITY OF MICHIGAN.

THE Department of Medicine and Surgery of the University of Michigan recently completed the fiftieth year of its existence; a brief review of the more important facts bearing on its establishment and development would therefore seem timely. The fact that this medical school was the first to be established as a department in a State University, and is now one of the very few medical schools founded in a comparatively small inland city, which has shown a constant growth from its beginning, gives it a unique position and must of necessity attach some interest to its history.

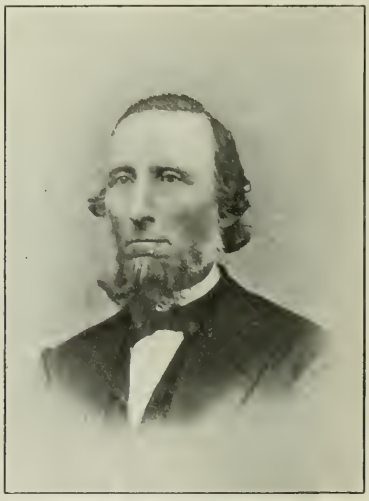
Medical Building, University of Michigan, as completed in 1865.

In an act, passed March 18, 1837, providing for the organization and government of the University of Michigan, we read in Section 8 that the University shall consist of three departments: (1) The department of literature, science and the arts; (2) the department of law; (3) the department of medicine. This Section further states that in the department of medicine there shall be established the following professorships: "One of anatomy; one of surgery; one of physiology and pathology; one of the practice of physic; one of obstetrics and diseases of women and children, and one of materia medica, and jurisprudence." No steps were taken, however, to carry out that part of this measure relating to the establishment of the medical department until 1847, when a committee of the Board of Regents, of which Dr. Zina Pitcher was chairman, urged its immediate organization; they reported at some length as to methods and aims, calling especial attention to the necessity of requiring an adequate preparation before the study of medicine was undertaken. The medical department was, however, not opened until October, 1850. The qualifications required for admission at the time of opening were "A good English education, the knowledge of natural philosophy, the elementary mathematical sciences, and such an acquaintance with the Latin and Greek languages as will enable the student to appreciate the technical language of Medicine and read and write pre-

scriptions." The course of lectures extended from the first Wednesday in October to the third Wednesday in April. Four lectures were given daily, except on Saturdays, which were occupied by the alternate hearing and criticism of these. To be admitted to the degree of Doctor of Medicine the student was required to show evidence of having pursued the study of medicine and surgery for the term of three years, including the time spent with a preceptor, attended two full courses of lectures, submitted a thesis and passed an examination held at the end of the term. An allowance of one year from the term was made in favor of college graduates.

Soon after the establishment of the Department of Medicine, the University of Michigan was singularly fortunate in obtaining as its first president Dr. Henry Philip Tappan, that prince of educators, to whom the educational system of Michigan, and indeed, of the country at large, owes so much. He entered upon his work at Michigan University after he had learned to appreciate the Prussian system of education. His broad conception of what a university should be has as yet been scarcely realized in America. To what extent his influence shaped the policy of the medical department in its early days, can now be only conjectured. It seems justifiable, however, to assume that the following passage which appeared for a number of years in announcements of the department of medicine during its early history, expressed his hopes and desires: "The Medical Faculty, in common with all the enlightened members of the professions, desire, earnestly, that a rule might prevail in our country like that which prevails in the Universities of Prussia, by which a liberal education should be made the necessary introduction to professional study. The Sciolist easily runs into the Empiric; but, he who has obtained a thorough scientific discipline knows how to discriminate between visionary conjecture and established truths."

Before the opening of the medical school in 1850 the Board of Regents authorized the erection of a medical building and a portion of the present home of the medical department was built, thus making provision for lecture rooms and the then necessary laboratories. A faculty composed of five professors had been selected sometime before the date of opening, of whom two, namely Drs. Sager and Douglas, were transferred from the faculty of the Department of Science, Literature and the Arts to that of Medicine. In the calendar of 1850-51 the first faculty was announced as follows: Abram Sager, A.M., M.D., President and Professor of Obstetrics and Diseases of Women and Children; Silas H. Douglas, A.M., M.D., Professor of Chemistry, Pharmacy, and Medical Jurisprudence; Moses Gunn, M.D., Secretary and Professor of Anatomy and Surgery; Samuel Denton, M.D., Professor of Theory and Practice of Physic and Pathology; J. Adams Allen, M.D., Professor of Therapeutics, Materia Medica and Physiology; R. C. Kedzie, A.B., Acting Demonstrator of Anatomy. This faculty was early strengthened by the addition in 1854 of Alonzo B. Palmer, M.D., Professor of Materia Medica, Therapeutics and Diseases of Women and Children; and Corydon L. Ford, M.D., Professor of Anatomy. In 1860, upon the death of Dr. Denton, Dr. Palmer became Professor of the Theory and Practice of Medicine, of Pathology and Materia Medica; Dr. Sager, Professor of Obstetrics and Diseases of Women and Children; and Dr. Ford, Professor of Anatomy and Physiology. An extended personal sketch of the members of these faculties, interesting and instructive

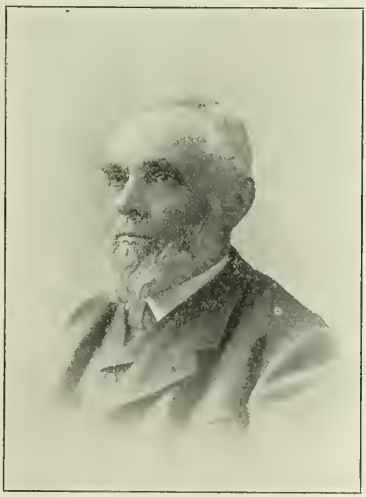


ABRAM SAGER.
(1850–1875)

though it might be, would lead the writer beyond the limits prescribed. Yet, since not bricks and mortar, but more especially able teachers make a real university, some brief reference to the worth of these men would seem fitting in this connection.

Dr. Sager was educated at the Rensselaer Polytechnic Institute, giving especial attention to Botany and Zoology; and subsequently extended his studies under Marsh and Ives, at New Haven. His medical education was obtained at New Haven, Albany and Castleton, Vermont, from which school he graduated in April, 1855. Soon after coming to Michigan, he was appointed chief in charge of the Botanical and Zoological Department of the Michigan Geological Survey. He served as Professor of Botany and Zoology in

this University from 1842 to 1850, after which time he became a member of the medical faculty. He was, however, not only a thoroughly trained scientist, truly imbued with the scientific spirit, but also a most skilful physician and dextrous operator, performing many major operations, among which may be mentioned a Cæsarian section, performed in the University Hospital in 1869. His medical writings contain frequent references to French and German literature and show a breadth of knowledge, which would be commendable even at the present time. He was for many years President or Dean of the Medical Faculty, and for a number of years gave the Lectures in physiology. "Dr. Sager's personal character, his eminence in his profession, and his faithful and able service to this University for thirty-three years were such as to place his name high among those whom it is the privilege of the University to honor."



SILAS HAMILTON DOUGLAS.
(1850–1877)

Dr. Douglas is especially to be remembered as one of the first teachers of science in America to appreciate and utilize the laboratory method of teaching. From its small beginning in 1856, the chemical laboratory soon grew under his wise management until for many years it deserved the reputation of being one of the largest and best equipped on this continent. This laboratory was open to medical students from its very beginning. (The work so ably begun by Dr. Douglas has been fostered and further developed by Professor A. B. Prescott, for a time his co-worker, then his successor, and now the oldest and most respected member of the present medical faculty.)

Dr. Moses Gunn was graduated from the Geneva Medical College in 1846. Soon after he came to Ann Arbor and gave a course of lectures on anatomy, accompanied by dissection and demonstrations. He, perhaps more than any other member of the original medical faculty, deserves the distinction of being called the father of the department which he helped to establish, and in which he labored so many years. The following brief eulogy, which I quote from the writings of another, describes admirably his bearing and worth: "Tall, manly and graceful in his bearing, with an eye which commanded and secured the respect of students and the obedience of patients, with well-developed forehead which proclaimed the owner's ability to plan and determination to win success, with a trained hand, which dared to do many operations, the

MOSES GUNN.
(1850–1864)

landmarks of which were not then described in the works of surgery." Of his writings, that on "The Philosophy of Certain Dislocations of the Hip and Shoulder, and their Reduction," is of interest in this connection, since the observations reported in this contribution were made while he was a teacher at Ann Arbor. His articles on this subject were reprinted in pamphlet form in 1859, and this "little pamphlet of less than 25 pages contains more learning than volumes that many others have compiled," as has been said by one of the foremost surgeons and writers of the present generation.

Dr. J. Adams Allen was for two years Professor in the La Porte Medical College before receiving his appointment at the University of Michigan as member of the first medical faculty. He was a most scholarly man and versatile lecturer. It was often said of him that he could with distinction have filled any chair in the department. It is of interest here to note, not only as concerns the history of the medical department of this University, but also the history of American medicine, "That the whole subject of reflex nervous influence, of which excito-motor and excito-secretory action are but constituent parts, was taught as early as 1850 in the University of Michigan," by J. Adams Allen, "and in his teaching and writings are to be found the only explicit and comprehensive exposition of the whole

ALONZO BENJAMIN PALMER.
(1854-1887)

subject of reflex nervous action that has ever fallen under my observation."

The death of Dr. Denton in 1860, removed him only too early from the midst of this remarkable group of men. Before becoming a member of the first faculty he had served with distinction as Regent of the University and as State Senator.

Dr. Alonzo B. Palmer was graduated in 1839 from the College of Physicians and Surgeons of the Western District of New York. Soon after graduation he came to Michigan, where for a number of years he led the arduous life of a country practitioner. The winters of 1847-8 and 1848-9 he spent in post-graduate work in New York and Philadelphia respectively, and during the former winter attended the courses of lectures on embryology given by Agassiz. In 1850 he established himself in Chicago and in 1853 was appointed city physician, which office he filled with great distinction during the severe cholera epidemic in 1854. In 1852 he received the appointment of Professor of Anatomy in the University of Michigan, which chair he was preparing himself to fill, when in 1854 he was called as Professor of Materia Medica, Therapeutics and Diseases of Women and Children. The years spent in general practice, his post-graduate study, his work as city physician in one of the largest of the then western cities, gave the inquiring and reflective mind of Dr. Palmer abundant opportunity to expand and mature, and fitted him for the work to which he had been called. Soon after coming to Ann Arbor his fund of information was further extended by post-graduate work in England, supplemented later by further visitations of European hospitals. The studious habits formed in his younger days developed with his years. He was a constant reader of the current medical literature of the day, and enthusiastically investigated all additions to the science and art of medicine. In his clinic, however, he was at his best. A most careful and accurate diagnostician himself, he constantly strove to establish similar habits in the student under his care. His method was to study each case thoroughly, rather than to exhibit many patients. Of his contributions to medical literature we may specially mention his "Science and Practice of Medicine," a work which appeared in 1883 and comprises two large volumes.

Dr. Corydon L. Ford graduated from the Geneva College of Medicine in 1842, and was at once appointed Demonstrator of Anatomy in that College. In 1846 he was elected to the same position in the newly established Medical Department of the University of Buffalo, and in 1849, Professor of Anatomy in the Medical School at Castleton, Vermont. Dr. Ford and Dr. Gunn were contemporary students and for a time roommates at Geneva. During these days, it is stated, Gunn often said, "I shall be Professor of Surgery in a medical school and you shall be Professor of Anatomy in the same institution." Happily this prophecy, unlike many prophecies, became true in 1854, when Dr. Ford entered on his work as Professor of Anatomy in this school, continuing until the time of his death, in 1894. Thus from the time of his graduation to the time of his death, for nearly three score years, he was a teacher of Anatomy, and as a teacher he excelled. He brought to the class room his store of knowledge, gathered not so much from books, as from personal observations, numerous preparations illustrating all phases of the topic discussed and a zealous enthusiasm, which was always imparted to his class, stimulating each student to become an eager listener and

a thoughtful and inquiring learner. His time was so occupied by teaching and the preparation of many valuable museum preparations, illustrating human and comparative anatomy, as to prevent his making many important contributions to medical science. It must be considered a most fortunate circumstance that both Dr. Palmer and Dr. Ford were able to labor more than a generation in this institution. The former for many years, in addition to his teaching, honored the deanship of the Department of Medicine, ever striving for its expansion and betterment and inaugurating many advances, the latter occupied the deanship during the closing years of his life. With these men labored for briefer periods, Dr. Edmund Andrews, for a time Professor of Comparative Anatomy and Demonstrator of

CORYDON L. FORD.
(1854-1894)

Anatomy and Dr. S. G. Armour, for a number of years Professor of the Institute of Medicine and of Materia Medica. With great wisdom and good judgment did this faculty inaugurate the work of this department.

In this brief sketch it will not be possible to do more than mention the names of men forming a part of the teaching force of the faculty of the Department of Medicine during the third and fourth decades of its existence; the transition period between the early faculty and the present one. In 1867-68 Dr. W. W. Green was Professor of Surgery. He was one of the first, perhaps the first American surgeons to extirpate the thyroid gland. In 1868-69, Dr. H. F. Lyster was Lecturer on Surgery. The following two years this chair was occupied by Dr. A. B. Crosby, a brilliant young surgeon, whose old coat—lest his better garment be soiled with blood—bore the marks of many major operations. He was succeeded in 1871 by Dr. T. A. McGraw, himself succeeded in 1872 by Dr. Donald Maclean. Dr. George E. Frothingham was appointed Demonstrator of Anatomy in 1867, Lecturer on Ophthalmology in 1870, later assuming the duties of Professor of Ophthalmology and Materia Medica and Therapeutics. In a comparatively short time, after he assumed the charge of the department of ophthalmology, it became a distinctive feature of the medical department. His interest in medical education caused him to take an active part in all attempts looking toward the general elevation of the standard of requirements for the degree of Doctor of Medicine. He resigned his place in the faculty in 1889. Dr. Henry S. Cheever was for a time Demonstrator of Anatomy and in 1870 was appointed Professor of Materia Medica and Therapeutics, which chair he occupied until 1876, when ill health compelled him to sever his connection with the department. Dr. E. S. Dunster was appointed Professor of Obstetrics and Diseases of Women in 1875, succeeding Dr. Sager. He was a learned teacher and a most brilliant lecturer, using the purest English, and arranging the subject matter most logically. In 1877 Dr. J. W. Langley was appointed Professor of General Chemistry in the medical department, which position he filled with distinction for about ten years. These and others that might well be mentioned here, did space permit, carried on the work, so well begun by their predecessors.

The number of students in attendance in this medical school has from the date of its opening to the present time, shown a steady and normal growth, presenting, however, one period in which the number showed a marked decrease. In 1850-51 there were enrolled 90 students, of which six received the degree of Doctor of Medicine at the close of the session. The enrollment increased rapidly in the succeeding years, reaching the number 525 in 1866-67. During the following ten years the registration decreased gradually, the year 1876-7 finding only 285 students in attendance.

The large number in attendance in 1866-7 (525) is in part accounted for by the fact that many young men, who, during the civil war acted as hospital stewards, entered upon the study of medicine soon after its close. The decrease in the number of students during the decade following 1866-7 has been attributed to the agitation resulting from an endeavor to establish a school of homœopathy in the University. This department was established in 1875. The proceedings of the Michigan State Medical Society, during the years in which this discussion was carried on, clearly reveal the attitude of the profession in Michigan toward this question. The American

Medical Association participated in the strife and for a number of years this matter was the subject of bitter discussion before this body. A settlement was reached at the Atlantic meeting in May, 1879, as a consequence of an able and most eloquent argument made by Dr. E. S. Dunster, then a member of this faculty. In order to appreciate the influence that this discussion had on the number of students enrolling in this department, it must be remembered that both the State and National Association attempted to prevent the graduates and teachers of this medical school from holding membership in these bodies. This was due to the fact that the grant made for the purpose of establishing a homœopathic department in this university was insufficient to provide for a full faculty and consequently

EDWARD SWIFT DUNSTER.
(1874-1888)

their students were required to receive instruction in the Department of Medicine in all the subjects not taught in the homœopathic department; hence the American Medical Association, "considered it derogatory for any physician or teacher to aid in any way the medical teaching or graduation of persons knowing them to be supporters and intended practitioners of some irregular or exclusive system of medicine."

Women were first admitted to the Medical Department in 1870, but for a number of years the instruction given the two sexes was separate, each professor after giving his lecture to the male students, repeating the same, in a small room, to the female students.

During the first and second decade of the existence of this department, the annual course of lectures was begun on the first Wednesday in October and continued until the third Wednesday in April. The candidate for a degree was required to have attended two full courses of lectures and to have spent one year with a practitioner. An allowance of one year from the term of study was made in favor of graduates of approved universities and colleges. In 1877 the course of study was extended to two years of nine months each and in 1880 three years of study of nine months each became necessary before a candidate could present himself for final examination. In 1890 the compulsory term of study was extended to four years of nine months each. The three years' course of nine months each allowed a graded curriculum to be established and the addition of a fourth year permitted further gradation and gave opportunity for extending laboratory teaching. The main features of the curriculum, in operation since 1890, have been sequence and concentration in the subjects presented, abundant laboratory teaching and general survey of each branch by means of lectures, recitations and demonstrations.

The qualifications required for admission were for many years essentially the same as those found in the first announcement. These were, as has been previously stated, a good English education, a knowledge of natural philosophy and of elementary mathematical sciences and of acquaintance with Latin and Greek. Greek was dropped from the list of entrance requirements in 1859. In 1890 the requirements for admission were advanced to a diploma from the classical or Latin course of an approved high school. This was modified in 1896 by requiring instead of a classical or Latin diploma, a certificate of having passed certain prescribed subjects. The list embracing a good knowledge of English, mathematics through geometry, general and American history, physics or chemistry, botany and zoology or biology, and Latin Grammar and Cæsar. To this list has been added plane trigonometry and a reading knowledge of either German or French, and in order to meet the entrance requirements in the sciences named, the entering student must now present a certificate showing that the courses pursued were accompanied by laboratory work. (A reading knowledge of both German and French will soon be demanded as an entrance requirement.) In thus specifying the subjects required to meet the entrance qualifications the aim has been to regulate as far as possible the education of those intending to pursue the study of medicine. The end desired, namely, a better training before the study of medicine is undertaken, would seem to be more readily attained by this means, than by making residence in a college or university for a prescribed period, without special reference to the curriculum pursued, a prerequisite to the study of medicine.

The importance of laboratory instruction was recognized by the founders of this department, and since its beginning this method of teachings has formed a prominent feature of its curriculum.

The first laboratory to be established was the anatomical, occupying rooms long since used for other purposes. Since 1880, by State enactment, provision is made for anatomical material. In 1856, a portion of the present chemical laboratory was built, and since that time medical students have received laboratory instruction in chemistry and the analysis of urine. In 1877 the Legislature voted $3,500.00 for the purpose of furnishing equipment for a histological and physiological laboratory. For a number of years the instruction in this laboratory was mainly in microscopic anatomy. In 1881 the study of physiology was further provided for by the appointment of Dr. Henry Sewall, first as Lecturer, then as Professor of Physiology. While in charge of this laboratory Dr. Sewall brought it into prominence by the publication of a goodly number of researches, not the least of which was one showing that pigeons could be immunized against the poison of the rattlesnake (1887). He was therefore one of the first to use a chemic agent in the production of artificial immunity. In 1878 an extended laboratory course in physiological chemistry was added to the curriculum. In the same year the laboratory of electrotherapeutics was established, the first of its kind in America. A laboratory course in this subject has been required of the students since 1890. In 1879 practical instruction in pathology was inaugurated. The Laboratory of Hygiene was built and equipped at the request of the Michigan State Board of Health in 1888. The objects as set forth in the memorial presented to the Board of Regents, were as follows: (1) Original research in the causation of disease: (2) the examination of food and water suspected of having caused disease; (3) the instruction of students. Since 1888 an extended course in bacteriology has formed a part of the required work of each student. The laboratory of clinical medicine was established in 1891, and was at that time the only officially recognized laboratory of its kind in America. Its primary function is that of carrying out the instrumental investigation of disease. Senior students have access to this laboratory and use it in working up the cases assigned them in the clinic. In 1892 was established the surgical laboratory, and as a part of his course each student performs laparotomies, ligates vessels, etc., on living animals, giving the same attention to antisepsis, asepsis and dressings as is bestowed on similar operations in man. In the same year was established the pharmacological laboratory. In this laboratory students are given the opportunity to study the effects of drugs on living animals and are taught the methods by which drugs are examined.

During the first two and one half years of his residence in this department each student spends four hours each afternoon, Saturday excepted, in laboratory work. The classes are divided into sections, each section working continuously for a given period in one laboratory, the sections alternating at the end of the laboratory period, each in turn taking up new work.

During the first few years of the existence of this department, clinical instruction received comparatively little attention. For a number of years after the opening of this school, the general announcement contained this statement, a portion of which might be read with profit even at this day: "The hasty walk through the wards of a hospital (necessarily hasty if entered upon at all during the lecture term) furnishes at best but a poor substitute for the close and accurate study of cases as they occur in the professional round of the private practitioner." It should be remembered that at that time a period of study under a preceptor formed a part of the educational requirements of a candidate for the degree of Doctor of Medicine. In 1857 there was established in Detroit in connection with this medical school, a school for clinical instruction, under the direction of Dr. Zina Pitcher and Dr. A. B. Palmer, the term beginning the 15th of June and ending the 30th of August. This course was, however, abandoned in 1859. In 1869 a large dwelling house on the college grounds was given to the medical department for a hospital building and was fitted up for that purpose. In 1876 two large pavilions were added to this building, thus greatly increasing the hospital facilities. The year 1891 saw the completion of the new University Hospital, situated a short distance from the campus. The faculty has thus had under its control for more than thirty years, a hospital which could be utilized without restriction for clinical instruction; the patients coming to the hospital with the full understanding that they would receive every care, but also, that they would be used for purposes of instruction in all legitimate ways. Students are taken to all the wards of the hospital, take histories, dress wounds, etc., and are able to study disease and observe treatment under the most favorable circumstances. In 1893 demonstration courses in clinical medicine, surgery, obstetrics and gynecology, ophthalmology and nervous diseases were inaugurated and became a part of the required work of each student. This work is given to the third year students, the class being divided into Sections numbering about twenty, each section confining itself for two hours, four times each week, for a period of six weeks to one department of clinical

work, at the end of which time the sections alternate and a new subject is entered upon.

The medical library of this University was started in 1854 by a special appropriation of $66.00. From this small beginning it has grown to a valuable working library of somewhat more than 10,000 volumes, not including a large chemical library. It now contains complete files of nearly all the important periodicals, academy reports, proceedings of societies, etc., pertaining to the science and art of medicine, published in this and foreign lands, also numerous handbooks and reference books and other works of interest to the student of medicine. The value of such a library will be readily appreciated by any one engaged in the pursuit of the science of medicine, for a good library is as essential to the research student as are laboratories or other facilities for the prosecution of such work.

ORIGINAL ARTICLES.

SOME ERRORS IN THE EXAMINATION OF URINE.[1]

BY LOUIS HEITZMANN, M.D.,
OF NEW YORK.

There are probably few practitioners who do not make examinations of urine more or less frequently, although chemical tests for albumin and perhaps sugar and microscopical examinations for casts are the only tests resorted to by the largest number. Whenever albumin is found a diagnosis of nephritis is unfortunately made by many without the use of the microscope; while others, who take the trouble to examine for casts, will, if the latter are not found, consider the case one of so-called "functional albuminuria."

Although the presence of albumin, even in small amount, is undoubtedly of some significance in every case, it does not necessarily follow that a lesion of the kidney must exist at the same time, since the presence of pus corpuscles, no matter from what cause, is sufficient to give a positive reaction. A mild cystitis, a urethritis, prostatitis or even a simple vaginitis may show albumin in the urine, while it is a well-known fact that even in grave kidney lesions, such as cirrhosis, the urine may at times contain such a minute amount of albumin as to escape detection completely, or it may even be entirely absent at certain hours of the day.

This being the case, it is plain that no diagnosis of nephritis should ever be made without the aid of the microscope, although the absence of casts, with the presence of a varying amount of albumin, does not exclude a kidney lesion; in cases of catarrhal or interstitial nephritis we rarely will find casts, and even in cirrhosis of the kidney, the termination of a chronic interstitial nephritis does not, as a rule, give casts in the urine.

Tests for albumin being so universally resorted to, it is surprising to see the large number of tests recommended as the best, and still more surprising to notice that occasionally two observers will not agree as to the presence or absence of albumin in a given case. While some continually recommend heat tests as the only reliable ones, others will tell you that only cold tests must be used, and give as their reason the precipitation of phosphates by simple heat and the fact that, unfortunately, some physicians will rely upon such heat tests alone in diagnosing the presence of albumin. Although different cold tests will undoubtedly show albumin when present in large amount, they will often not show it when present in small quantities only; the errors made with such tests are great since different substances may also give a reaction similar to that for albumin.

Heat tests are under all circumstances the most reliable, provided that acids are used to differentiate between phosphates and albumin. The acid most frequently used for this purpose—nitric acid—should, however, not be employed, since, if small amounts only of albumin are present and too much acid be added, no precipitation takes place. It is of the greatest importance in many cases that even the faintest traces of albumin be discovered, and the most reliable test for this purpose is heat and acetic acid. After boiling the urine thoroughly, two or three drops of a solution composed of equal parts of glacial acetic acid and water should be added, and, if no pronounced precipitation takes place, some unboiled urine poured into a second test-tube, the two being thus compared in a moderately strong light. In this manner even the faintest traces of albumin will at once become apparent, when they would not be found with any other test. Pure glacial acetic acid must not be used, the same objection holding good here as with nitric acid.

Since albumin will usually be found when pus corpuscles, even in comparatively small numbers, are seen under the microscope, we can soon convince ourselves by different tests, that the acetic acid is the most sensitive of all, giving a positive reaction where other tests fail. In cases of hyperemia of the kidney, or irritation of the pelvis of the kidney, due to lithemia or oxaluria, which as a rule contain only traces of albumin, these are frequently not discovered with the nitric-acid test.

Chemical tests for albumin are undoubtedly of the greatest practical importance, but microscopical examination of the urinary sediment is no less so, and it can never be sufficient to look for casts only and to pay no attention to the other features. Casts, however, being most commonly examined for, and supposedly universally known, it seems hardly possible that differences of opinion as to their presence in a given case should exist, yet this is so. We hear it stated that, although true casts are most commonly found in pathological lesions of the kidney, they may be seen in individuals in whom the kidneys are perfectly normal and no other features whatever can

[1] Read before the Medical Association of the Greater City of New York, November 12, 1900.

be found in the urine, as well as in pathological conditions of other organs, and even as coming from the seminal tubules. If this is correct, we do not as yet know what casts really are. The difficulty seems to be in not differentiating between true and false casts. True casts can only be derived from the uriniferous tubules when a pathological condition exists in the kidneys, and are the products of an albuminous and fibrinous exudation from the blood-vessels and of broken-down and disintegrated epithelia from the tubules. With the exception of waxy casts, their structure is the same, whether they are purely hyaline, or contain upon them epithelia from the uriniferous tubules, red blood-corpuscles, granules or fat globules.

Hyaline, epithelial, blood, granular, fatty and waxy casts are the only true casts, the first three being found in acute, the latter three in subacute and chronic inflammations. True granular casts are disintegrated epithelial casts, and we frequently see the remains of epithelia upon them. Such casts, as a rule, are never found until the inflammation has lasted six weeks or two months, although exceptionally, especially in cases of nephritis after contagious diseases, such as scarlet fever and diphtheria, they can be seen in small numbers in the second or third week of the kidney lesion.

Fatty casts are secondary products of previous epithelial and granular casts, the fat globules being secondary changes of the granular protoplasm, and when present in large numbers denote not only chronicity, but also a fatty degeneration of the kidney. Waxy casts, which are chemically different from the other true casts, always indicate a waxy or amyloid degeneration of the kidney, and are found in chronic constitutional diseases, such as tuberculosis and syphilis. It is an error to suppose that such casts have no special significance, can be found in acute inflammations, or even, as stated in some text-books, without any inflammation whatever.

In speaking of epithelial casts, we mean only hyaline casts, containing upon them a varying number of epithelia from the uriniferous tubules, and not simple conglomerations of epithelia resembling casts. So-called pus casts, that is, conglomerations of pus corpuscles, cannot be called casts at all. In epithelial casts the epithelia will be different when the cast comes from the convoluted, the narrow or the straight collecting tubules. The convoluted tubules of the kidney are lined by cuboidal, the narrow tubules by flat, and the straight, collecting tubules by columnar epithelia.

Casts vary greatly in size, the smallest or rather narrowest being those from the narrow or looped tubules; the second size those from the convoluted tubules of the second order or distal convoluted tubules; while the largest come from the straight, collecting tubules. Casts from the proximal convoluted tubules or those of the first order, directly emanating from the tufts, are never found in urine, since they cannot pass the looped tubules. These sizes are undoubtedly of value in determining the prognosis of a given case. When small casts from the narrow tubules are present alone, the case is, as a rule, a comparatively mild one; when a moderate number of casts from the convoluted tubules are found with those from the narrow tubules the case is of moderate severity, while casts from all three tubules, especially a large number of those from the straight, collecting tubules, denote an intense case with a doubtful prognosis.

From what has been said about the nature of true casts, it is perfectly plain that they can never be found in urine without some other evidences of an inflammation, such as pus-corpuscles, red blood-corpuscles and epithelia. Not infrequently, however, we read reports of urine examinations, which state that no albumin is present, pus-corpuscles, red blood-corpuscles and epithelia are absent, but hyaline and granular casts found in varying numbers, and a diagnosis of a parenchymatous nephritis given. If we examine such urine carefully, we will see a small or moderate number of pale formations, which at first glance resemble hyaline casts, but which, if focused sharply, will be found traversed by extremely pale, fine threads, which may become plainly visible only after shading the light to a certain degree. These formations are not true casts at all, but cylindroids or mucus-casts, that is, mucus-threads resembling casts which may be derived from any portion of the genito-urinary tract, such as the bladder, prostate gland or vagina, and are therefore entirely independent of a nephritis. Mucus, normally present in every urine, is always increased in irritations or inflammations, more especially in those from the genital tract.

Although such cylindroids are at times quite long and irregular, tapering to a thin thread, they may be much more regular and then great care must be taken not to mistake them for hyaline casts, the more so since these latter, principally those from the looped tubules, may also be long, somewhat irregular and convoluted. It is, therefore, important to satisfy oneself of the nature of these formations, before diagnosing them as hyaline casts.

Not only are hyaline casts frequently said to be present when they are not, but the same is true of granular casts. It is well known that bacteria of a harmless character are often found in urine, especially in warm weather and in the urine of females. These bacteria can conglomerate upon mucus, and will then resemble granular casts, while in reality we have to deal with so-called bacterial casts only. In such cases mistakes can easily be avoided if the same care is taken as when looking for hyaline casts: sharp focusing will at once tell us that we have no granules, but cocci which have formed into masses. Individual cocci, as well as irregular groups, which are always present in such cases, still further clear up the diagnosis.

Cases in which these mistakes are made are, unfortunately, common, and not rarely perfectly

healthy individuals are told that they suffer from a nephritis. A short time ago, a stout healthy young man, who had never been ill in all his life, and who was refused by a life insurance society on account of alleged presence of albumin and casts in the urine, was sent to the author by his physician for a diagnosis as to the condition of his kidneys, since there were no clinical symptoms whatever, to bear out the diagnosis of a nephritis. Upon examination of the urine, an excess of phosphates was found, but not a trace of albumin, no pus-corpuscles, no epithelia and no casts, though a small number of cylindroids and bacterial casts was present. The only chemical test resorted to in this case had been simply boiling, without the addition of any acid, and in the microscopical examination the absence of any evidence of inflammation was entirely disregarded.

Within the last few years the centrifuge is being considerably used in urinary examinations and mistakes are frequent. Both mucus and bacteria are abundantly found after centrifuging the urine, and cylindroids are met with more frequently. Since the centrifuge presents no advantages over the old method of allowing the urine to stand at rest for six or twelve hours, it should not be used, with the sole exception of examining for tubercle bacilli, which latter are undoubtedly more easily found in centrifuged urine, the centrifuged sediment showing bacteria in larger numbers than non-centrifuged specimens. Pus-corpuscles, epithelia and casts are just as abundant after natural sedimentation, and the errors considerably lessened.

Finally, it should be pointed out that the diagnosis of a nephritis does not necessarily depend upon the presence of casts in the urine, since these are almost invariably absent in interstitial nephritis. Pus-corpuscles, red blood-corpuscles and kidney epithelia are sufficient for a diagnosis, the latter being invariably one-third larger than the pus-corpuscles in a given case, and are the same as those found in epithelial casts. Such epithelia are never voided in health, and if care is taken to look first for pus-corpuscles, which are always the smallest granular corpuscles, mistakes cannot be made.

ACUTE TRAUMATIC MALIGNANCY.

BY WILLIAM B. COLEY, M.D.,
OF NEW YORK.

(Concluded from page 580.)

Case VIII.—Spindle-Celled Sarcoma of the Thigh.—H. M., female, aged thirty-nine years, with good family history. The patient struck the right thigh against the corner of a lounge in December, 1898. The region of the injury continued more or less painful and two weeks later a swelling was noticed which grew rapidly until December, 1899, when it had reached the size of a fist and was removed. There was a local recurrence in February, 1900. This grew rapidly and in June, 1900, was as large as a child's head. It was again removed. Microscopical examination showed the growth to be spindle-celled sarcoma. The disease returned in October, 1900, in spite of local treatment with the mixed toxins, and amputation just below the trochanter was performed on October 24, 1900.

Case IX.—Sarcoma of the Testis.—F. H., aged twenty-seven years; good family history. Was kicked by a horse in the right testis in August, 1896. One week later he noticed a hard, slightly painful nodule in the upper part of the testis. This did not increase in size much until a year and a half later, when he fell through a hayrack, again bruising the same testis. The testis was sore the following day, and one week later the patient noticed a marked increase in size of the old nodule. The tumor continued to grow rapidly, but was practically painless. In four months it had reached the size of a fist. I performed a very radical operation, opening up the inguinal canal and removing the cord beyond the internal ring. Although there was no apparent involvement nor enlargement of the glands, the disease recurred within the abdomen, and the patient died one year later. The tumor was a round-celled sarcoma.

Case X.—Sarcoma of the Groin.—C. D. C., male, aged thirty-nine years; good family history. Received a severe blow in the left groin on the sharp corner of a table. A small lump appeared at the site of the injury almost immediately, and never disappeared. There was but little increase in size during the year following, but at the end of this time it began to grow more rapidly until at the end of six years, it had reached the size of two fists, extending from the root of the penis to the anterior superior spine. It was removed by Dr. Armstrong, surgeon of Cawnpore, India. Although the disease was supposed to have been entirely removed, local recurrence quickly followed and within a few months there was evidence of metastatic invasion of the liver.

Case XI.—Sarcoma of the Upper Jaw.—M. H., male, aged twenty-four years; always in good health until March, 1898, when, while having a tooth pulled, a portion of the jaw was broken off just below the antrum. Two to three weeks later a tumor was noticed in the region of the injury. This increased rapidly in size and a few weeks later it was removed by Dr. J. D. Spencer, of Watertown, N. Y. The tumor proved to be a spindle-celled sarcoma of very rapid growth and high malignancy, closing with a fatal issue within a year. In this case it is possible that the disease existed prior to the injury, although the weight of evidence is against it.

Case XII.—Sarcoma of the Metacarpal

Bone.—B. D., female, eighteen years of age. No history of heredity, and in perfect health upto August, 1890, received a severe blow upon the back of the right hand from a revolving chair in a parlor-car. A slight swelling appeared immediately. At the end of a week, instead of having decreased, it has slowly increased and become very painful. The patient consulted several physicians, but it was regarded as nothing more than a contusion. I first saw her in September, 1890, about six weeks after the injury. The wound then had the appearance of a periostitis, but incision under ether failed to find pus. Shortly afterward a piece of tissue was removed for microscopical examination, and it was found to be an alveolar round-celled sarcoma. A few days later I amputated at the middle of the forearm. Four weeks later there was a general recurrence and death followed six weeks later. This is a striking example of acute traumatic malignancy, because the tumor appeared almost immediately after the injury in a person in perfect health.

Case XIII.—Melanotic Sarcoma of the Thumb.—W. J. W., male, thirty-seven years of age. Perfectly well, with a marked hereditary history of cancer, three of his father's brothers having died of malignant disease, one of sarcoma of the shoulder, the other two of cancer of the tongue. On December 7, 1892, the patient injured his left thumb by getting it caught in a heavy office curtain; it immediately became swollen and painful. The swelling not subsiding, it was lanced on January 15th, and some pus evacuated. It continued red, swollen, and painful, and the root of the nail gradually became dark-colored. On May 15th a piece of tissue was examined microscopically, and found to be melanotic sarcoma, round-celled. The thumb was amputated by Dr. L. L. McArthur, of Chicago, on June 6th. Subsequent history: October 1st, a small, subcutaneous recurrence appeared in the forearm. Others followed in quick succession; during the next year more than 200 similar tumors were removed. The patient died in December, 1895.

Case XIV.—Sarcoma (Cylindroma) of Breast.—S. B., fifty-five years of age. Mother died of cancer at the age of sixty-seven, and grandmother died of a cancer of the uterus. The patient received a severe blow to the right breast in August, 1893, falling forward in an omnibus against the sharp end of an umbrella. One week later she noticed a contraction in the tissues at the site of the injury. Five or six weeks later a small bloody discharge appeared at the nipple. The induration and discoloration slowly increased, and in the following February, or five months later, the entire breast and axillary glands were removed. Recurrence quickly followed. During the next two years five or six other operations were performed for small local recurrences. Death followed shortly after an operation in August, 1896.

Case XV.—Sarcoma of the Breast.—M. M., female, aged thirty-one years, unmarried, with good family history, struck her breast against an iron bracket while acting as clerk in a dry-goods store. She noticed a swelling immediately after the injury, and this continued to increase in size. Five months later the tumor was removed by operation, recurrence quickly following; four months from the first a second operation was performed. The patient died eighteen months after the injury, from a supposed recurrence in the brain, five operations having been performed in the meantime. This case was operated upon by Dr. B. Gallaudet and Dr. William T. Bull; it was not seen personally by myself. It is of interest as it has an important bearing on the following case:

Case XVI.—Sarcoma of the Breast.—A. M., female, aged thirty-one years, a sister of the preceding case. The patient had always been in perfect health until August, 1896, when she received a blow upon the right breast. A few days afterward she noticed a lump at exactly the site of the injury. This grew rapidly, but it was not painful until November. In December, 1896, it became exceedingly painful and was growing with great rapidity. She consulted a physician, who advised internal treatment. On February 8, 1897, I saw her in consultation with Dr. William T. Bull. At this time the entire right breast was occupied by a spheroidal tumor about the size of a large cocoanut, markedly protuberant, slightly fixed to the chest wall, not involving the axillary glands. The skin was thin and glossy, and of a deep purple color over the most protuberant parts. The tumor grew with enormous rapidity and soon began to slough. The patient died of exhaustion in April, 1897, or seven months after receipt of the injury. It is of interest to note that in these two sisters the sarcoma developed immediately after an injury in both cases, the tumor occupied the right breast in both instances, and both were just thirty-one years of age at the time when the tumor developed.

Case XVII.—Sarcoma of the Femur.—J. N., female, aged eleven years, with good family history, had always been perfectly well until February, 1897, when she fell down a flight of stone steps striking upon the left knee. Pain and swelling immediately followed and continued over the outer condyle of the left femur. This grew rapidly and soon began to affect her general condition. Examination on July 28, 1897, or five months after receipt of the injury, showed the lower end of the right femur greatly enlarged, its circumference being sixteen inches while the corresponding measurement on the other side was ten inches. I amputated at the hip-joint on July 31st, at the Post-Graduate Hospital without previous exploration. The patient made a good recovery.

Microscopic examination showed it to be a spindle-celled sarcoma.

Case XVIII.—Round-Celled Sarcoma of the Testis, Following Bicycle Injury.—G. S., male, twenty-nine years of age, with good family history, always perfectly healthy, received an injury to the left testicle from a bicycle fall in August, 1896. A swelling appeared in the testis in September and increased rapidly in size. The first operation was performed in June, 1897, by Dr. Millbank of Albany. Speedy recurrence in the cord and inguinal glands followed. Four operations have been since performed, two by myself, The erysipelas toxins were tried for three or four weeks without effect. The tumors recurred and the patient died a few months later.

Case XIX.—Round-Celled Sarcoma of the Testis Following Bicycle Injury.—E. K., male, twenty-two years old, good family history, previously in perfect health. On attempting to learn to ride a bicycle, July 1, 1896, he fell and injured the left testis. Within one week after he noticed an increase in size; the increase continued, but the growth was not painful. In August, 1896, it had reached the size of a fist. In May, 1897, the patient was operated on and the tumor removed. Recurrence followed in May. A second operation was performed in June, 1897. There quickly followed abdominal recurrence; the patient lost flesh and strength very rapidly, and died early in October, 1897. Autopsy showed nearly all the abdominal organs extensively involved. After generalization had occurred the erysipelas toxins were tried ten days with little effect; only very small doses could be borne.

Case XX.—Sarcoma of the Axilla.—P. W., female, aged twenty-seven years, with a good family history, cut her hand upon a flower-vase three years ago. The hand was kept bandaged for two weeks. During this time a lump appeared in the axillary gland of the same side. This lump never disappeared, but slowly increased in size and at times was quite painful. Later on two other similar tumors appeared, and finally the three coalesced, forming one, the size of an orange. In January, 1896, the patient was operated on by Dr. A. J. McCosh, of the Presbyterian Hospital. It was found impossible to remove the entire tumor. The growth subsequent to the operation was exceedingly rapid, and the tumor soon involved the clavicle and portion of the scapula. Microscopic examination showed the tumor to be round-celled sarcoma. (This case can hardly be classed as a result of direct trauma.)

Case XXI.—Sarcoma of the Parotid.—W. M., male, fifty-six years of age; farmer; had always been well; no history of heredity. In the latter part of July, 1895, he received a blow in the right parotid region from a horse's head, the horse turning suddenly, while he was standing near him. One month later a small tumor, about the size of a hazel-nut, appeared at the site of the injury. This was removed under cocaine on October 6th. The tumor recurred almost immediately. A second operation was performed the last of October. On November 13th the tumor had recurred again, and reached the size of half an egg, involving the soft parts in the region of the parotid, but was not attached to the bone. A very thorough removal was made under ether anesthesia, but in spite of this in less than three weeks the tumor had recurred, and reached the size of half an orange. Microscopic examination showed the growth to be made up of mixed (round and spindle) cells, the round predominating. He was treated with the mixed toxins of erysipelas without result. This case is important as the tumor appeared within a few weeks after receipt of the injury. Four operations were performed within the following four months, showing a very high degree of malignancy.

Case XXII.—Round-Celled Sarcoma of the Femur.—Periosteal.—H. G., male, twenty-six years of age, with good family history, first noticed a swelling in the lower end of the femur in September, 1895. He had sprained his knee two months before while attempting to separate two large dogs engaged in a fight. The lameness and stiffness appeared at once, and it remained until the tumor was noticed, a few weeks later. Exploratory incision showed the tumor to be round-celled sarcoma, and a few days later amputation of the leg at the hip-joint was performed by Dr. William T. Bull. The tumor recurred in the stump and pelvis in March, 1896, and the patient died about five months later.

Case XXIII.—Osteosarcoma of the Lower Jaw.—H. D., female, aged thirty-eight years, received a slight injury to the lower jaw in June, 1893. Two weeks after the injury a swelling appeared at the site of the injury in the region of the first molar tooth; there was little pain. The tumor gradually increased in size, and in November was removed by Dr. A. Vandeveer, of Albany, a portion of the jaw being resected. About three months later the tumor recurred, soon involving nearly all the structures on the left side of the face.

Case XXIV.—Spindle-Celled Sarcoma of the Foot (Metatarsal Bone).—F. K., female, aged sixteen years, in 1888 had a fall, injuring the right foot. Shortly afterward two lumps appeared on the foot in the region of the injury, and in 1889 the patient was operated upon in the New York Hospital, by Dr. William T. Bull. The third and fourth metatarsal bones were removed. Three years later she received another injury of the foot, and a short time afterward a recurrence was noticed. Syme's amputation was then performed by Dr. Bull. In 1893 she fell downstairs, injuring the stump, and shortly after this a lump appeared on its outer aspect and slowly increased in size.

Soon afterward a tumor appeared in the popliteal space, and grew with great rapidity, until, in December, 1893, it had reached the size of a child's head, and was then removed by Dr. Bull. The small tumor in the stump was treated by Dr. Bull and myself with the mixed toxins of erysipelas, with the result of entire disappearance. About one and a half years later there was a return in the same locality, and in 1896 I amputated the leg just above the middle of the thigh. There have been two recurrences in the gluteal region, which have been removed by operation. The patient has had the toxins administered at intervals during three years. She is at present, March, 1901, in good health.

Case XXI.—Round-Celled Sarcoma of the Tibia.—S. L., female, twenty-four years of age; family history good; previous personal history contained nothing worthy of note. In 1895 the patient fell downstairs and injured the upper part of the right tibia. A swelling in the region of the injury quickly followed and was accompanied by considerable pain. The trouble slowly grew worse. For a number of months it was treated as a periostitis and later was regarded as an osteitis. The swelling slowly increased as well as the pain. A portion of the growth was removed for microscopic examination. The latter proved it to be a round-celled sarcoma. On August 27, 1896, I amputated at the junction of the middle and lower thirds of the thigh. (In this case the tumor developed immediately after receipt of the injury.) She was alive three years after operation.

Case XXII.—Sarcoma of the Kidney.—J. C. S., male, aged fifty years; German; perfectly well until March, 1893, when he fell down a flight of stone steps severely injuring the back just over the right kidney. About six months later hematuria developed. On the 1st of December of the same year a tumor could be made out in the region of the right kidney; operation was performed by Dr. F. Lange. The kidney was removed, the pleural cavity opened, and a portion of the twelfth rib resected. The patient was in the hospital for six weeks. He remained perfectly well for nearly four years after that, till March, 1897, when he had an attack of grip, which left him with some bronchial irritation. In May, 1897, while taking a cycling trip, he had slight dyspnea and considerable pain in the region of the old cicatrix. On July 5, 1897, a swelling was first noticed in the region of the old scar; this rapidly increased in size until November 24, 1897, when physical examination showed a tumor in the right lumbar region, extending from the crest of the ilium upward to the free border of the ribs, a distance of five inches. Transverse semicircumference of the tumor is six inches. The tumor occupies the site of the kidney, projecting somewhat beyond the level of the surrounding tissues, and is fairly well fixed. The skin over it is normal in appearance and not adherent. The patient has lost about ten pounds in weight and is in fairly good condition. There is no clear evidence of invasion of the pleural cavity. The erysipelas toxins were tried three weeks without result.

Case XXIII.—Melanotic Sarcoma of Foot.—J. H., female, aged thirty years; family history good. Had had a small movable swelling about the size of a dime on dorsum of left foot since childhood. It was not dark-colored and caused no inconvenience, until about three years ago, when the patient met with the following injury: While walking over a sidewalk undergoing repairs, her husband, preceding her, stepped upon a loose plank, causing the rear end to rise up two or three inches. Against this plank she struck her left foot, and shortly after, a week or two, she noticed the small lump was increasing in size. In a few months she had to get larger shoes, and the lump began to grow dark-colored. Ten months ago a tumor appeared in the groin, and this increased more rapidly than the tumor in the foot. She was admitted to the New York Hospital November 15, 1897, and the tumor of the foot was removed by Dr. Bull. The tumors of groin and pelvis were inoperable. The microscopic examination showed the growth to be a spindle-celled melanotic sarcoma with a great abundance of pigment. Dr. Bull transferred the case to my service at the New York Cancer Hospital for a trial of the mixed toxins. The patient was weak and had a daily temperature of 102° or 103° F., and only small doses of the toxins were given for two weeks. No effect was visible on the tumors. Two months later she developed spinal paraplegia.

Case XXIII.—M. C., female, aged fifty years; family history good. Patient had had a small, dark-colored congenital mole on outer aspect of left leg since infancy. In June, 1897, she scratched this, causing it to bleed. Almost immediately afterwards it began to grow. A short time later the tumor was excised. Speedy recurrence followed, both locally and in the upper portion of the thigh. The tumors grew with great rapidity, and on February 1, 1898, were entirely beyond operation. They were deeply pigmented.

Case XXIV.—Multiple Sarcoma.—M. F., female, aged forty-six years, with good family history, had a congenital mole upon the neck. This remained stationary until eight years ago, when it was scratched. It immediately began to increase in size, and when about as large as a hickory-nut, an attempt was made to remove it by a silk thread. Five years later a hard lump formed underneath the scar and grew slowly. This was thoroughly removed by operation. One year later a tumor developed in the axillary region on the same side. Two other tumors soon after appeared in the left buttock, one growing rapidly, the other re-

maining stationary. In August, 1895, there was a tumor, the size of a fist, just under the right breast attached to the skin, but apparently not connected with the breast gland; it was of a deep purple color. In the left buttock there was a similar tumor about the size of a cocoanut. This was probably a melanotic sarcoma.

I would like to mention, briefly, two histories of acute traumatic malignancy in carcinoma of the breast:

Case XXX.—Sister M., aged sixty years, in February, 1898, received a severe blow on the right breast from the elbow of a patient. She stated at the time, she knew this would result in cancer. Within four to five weeks she noticed a swelling at the site of the injury, together with sinking in of the nipple. The indurated area at this time was three inches in diameter. There was a feeling of heat in the region, but no pain. The tumor increased with great rapidity, and on October 9th, or about six months after the disease was first noticed, it had reached the size of a child's head, the skin over the entire area being indurated and infiltrated. The tumor was clearly inoperable. She was seen in consultation by Dr. Wm. T. Bull and the clinical appearances showed that the tumor was unquestionably carcinoma, although no microscopical examination was made. Curiously enough she stated that her first cousin had died of cancer of the breast, developing soon after a blow which she received from striking against the corner of an embroidery frame.

Case XXXI.—The following case, aside from the fact of its traumatic origin, is the only one I have observed of so-called disseminated schirrous or acute miliary carcinosis. Mrs. R., thirty-seven years old, married, born in Germany, without any history of heredity, received a hard blow upon the right breast from a bedpost in October, 1897. A few weeks later, she noticed a reddish discharge from the nipple of the injured breast. Shortly afterward she observed a hard lump at the site of the injury. This grew very rapidly, and in four months was as large as two fists. Not only was the entire breast involved in the disease, but the skin over the breast and a considerable area beyond was filled with typical, multiple carcinomatous nodules about the size of a split pea. The disease quickly extended to the other breast, and a few months later the skin over both breasts and the tissues over the entire front of the thorax were involved. The disease ran a rapid course, and the patient died eight months from the time the tumor was first noticed.

New Smallpox Pavilion.—A new smallpox pavilion will be built on North Brother Island. The building will be of frame construction, and will cost $10,000, according to the estimate of the architects.

EPISTAXIS.[1]

BY CHARLES N. COX, M.D.,
OF BROOKLYN, N. Y.

Etiology and Pathology.—Epistaxis, or bleeding at the nose, is in most cases a comparatively trivial affair. But it may involve grave danger to health or even to life itself. It may arise from some systemic condition or, what is most frequent, be due to some local morbid condition within the nasal cavities.

Some of the general conditions which may cause bleeding from the nose are, plethora, anemia, the hemorrhagic diathesis and organic disease of the heart, liver, or kidneys. It occurs in certain acute diseases, especially typhoid fever. Classical descriptions of the latter disease usually include epistaxis as one of its initial features.

But it should ever be borne in mind that the majority of cases of nasal hemorrhage are due to some intranasal lesion; and that the ultimate cure of such cases is dependent upon a localization and removal of the lesions. These may be due to traumatism or to some diseased condition within the nasal cavities.

The most frequent injury which gives rise to epistaxis is a blow or fall upon the nose. In such a case, some of the minute vessels of the mucous membrane lining the nose are ruptured, as a result of the violence of the concussion. If the blow be heavy enough, fracture may ensue, in which event hemorrhage may be very severe. Traumatism due to operation within the nasal cavities is almost invariably followed by hemorrhage. But it is usually controlled without difficulty. The most frequent seat of hemorrhage due to local causes is the triangular cartilage of the septum, just within the vestibule. This is very easy of access; the bleeding-point can be seen without difficulty and the means of arresting hemorrhage are easily applied. When bleeding occurs in this locality, it is totally unnecessary to pack the whole nostril, which is so often done—even to the extent of applying plugs posteriorly.

A very common cause of bleeding from this area is a deviation or spur of the septum so situated that the column of air in breathing causes undue dryness and discomfort, the result being that the patient is impelled to blow the nose inordinately, or even to pick the nose to remove the little crusts that form on the mucous membrane. This violence gives rise to superficial abrasions, minute vessels are ruptured and bleeding follows. In the course of time, these abrasions deepen to ulceration, nutrition is impaired, and sometimes the septum is actually picked through and a perforation results.

Varicose enlargement of the veins of the septum is a cause of severe hemorrhage occasionally. I have seen a few cases of minute angiomata, also, that bled violently, upon rupture. In one case that I saw in consultation the patient was almost exsanguinated, in spite of anterior and

[1] Read before the Queens-Nassau Medical Society, Oct. 30, 1900.

posterior plugging performed by the attending physician in a most perfect manner. Upon removing the plugs and mopping out the nasal cavity, I easily discovered the point of rupture, through which blood was spurting in a stream about the diameter of a small pin, with such force as to strike the turbinated body opposite.

Tumors may cause hemorrhage, but intranasal growths, fortunately, are comparatively rare, with the exception of mucous polypi and these seldom bleed. Of all the intranasal growths, sarcomata and fibromata are most apt to give rise to hemorrhage. Bleeding from the nose in children may sometimes be caused by lymphoid hypertrophy at the vault of the pharynx, or adenoids. But nasal hemorrhage from this source is seldom, if ever, severe. Vicarious epistaxis sometimes takes place in women at the time of the menstrual period, and is usually considered salutary when the flow of blood is not too great.

Treatment.—In the treatment of epistaxis, the first thing that demands our attention, no matter what the cause, is the immediate control of the hemorrhage, provided the flow is excessive and not accomplishing any good purpose. To do this intelligently, it is of importance to find, if possible, the spot from which the bleeding arises. This object cannot well be accomplished without good light and proper means of dilating the nostrils and illuminating the nasal cavities. To effect this, it is only necessary to employ the ordinary forehead mirror, a nasal speculum of some sort and a candle or lamp. Diffused daylight is usually not sufficiently powerful to illuminate the nasal cavities to the degree that is necessary for diagnostic purposes.

Unless bleeding has actually ceased when the patient is seen—in which event it is sometimes well to wait and see if Nature has not already controlled the flow by means of the clots which have formed—the bleeding nostril should be cleared by gentle blowing, followed by mopping with absorbent cotton on the end of an applicator. In a large proportion of cases, the source of bleeding can thus be seen, and it only remains to place some sort of a tampon over the leak in such a manner as to be retained in place and to make firm pressure. For the more severe forms of bleeding, local syptics are of little or no avail and should not be relied upon when we have at our command the more rational means of mechanical pressure.

Should the hemorrhage be so profuse as to well out so copiously as to defy any attempt to locate its origin, it may become necessary to resort to guess-work and plug the whole nostril. To accomplish this I prefer to use long strips of plain, sterile or iodoform gauze, about ½ inch or ¾ inch in width, passing one end of the strip through the nostril, by means of delicate forceps or probe, almost to the posterior pharyngeal wall, and then introducing successive instalments until the whole cavity is filled from behind forward. This, if properly done, will generally arrest hemorrhage from any portion of the nasal cavity and preclude the necessity of posterior plugging, which is, at best, almost intolerably painful to the patient and at times fraught with considerable danger to the Eustachian tube and middle ear.

I have seldom found it necessary to introduce posterior plugs. If necessity demand their application, it may be done in the following manner: First, prepare the tampon by taking a piece of gauze or absorbent cotton of sufficient size, so that when it is properly folded it shall be about 1¼ inches long and ¾ inch in diameter. Tie firmly around its middle a stout cord or silk ligature, leaving two free ends, each about fifteen inches long. Next, secure a thread or silk ligature ten or twelve inches long to the eye of a soft catheter. Pass the catheter along the floor of the nose and push it gently backward until it appears below the soft palate. Grasp the thread with a pair of forceps or hook, and draw it out of the mouth. Secure it to one of the tampon cords. Then withdraw the catheter and its thread from the nose. When the free end of the tampon cord appears at the anterior naris, make traction upon it, and draw the plug up behind the soft palate, assisting the operation by placing the index finger in the nasopharynx, and guiding the plug to its place over the posterior naris or choana. The cord hanging out of the mouth should be led to the ear and secured there, to facilitate removal of the tampon when the time comes. The cord in the nose should likewise be secured in some suitable manner, so as to prevent the plug from slipping out of place. The nasal cavity should then be filled with gauze in the manner heretofore described.

Rubber finger-cots have been recommended as an aid in packing the nose. One is to be passed well within the nasal cavity with a probe, and then filled full of cotton or strips of gauze. It might be possible to tie the open end with a ligature, and then distend the cot with air or water. These cots are usually about two inches long; therefore, pressure cannot be exerted beyond this distance.

Bernay's sponges of compressed cotton are also used for tamponing the nose. Their expansion incident to absorption of moisture is considerable; so that they exert strong pressure. A special form is made for application within the nasal cavities, but the ordinary ones also do very well for this purpose.

The patient should now be kept perfectly quiet, in a semirecumbent position. If the bowels are not moving freely and the subject be of full habit, a saline purgative may be administered with advantage. Under certain conditions, it may be proper to give ergot internally—say 10 to 20 minims of the fluid-extract, every two or three hours; or gallic acid, in 10- to 20-grain doses.

In the milder forms of epistaxis, some local astringent, styptic or caustic application may suffice to stop the bleeding. While alluding to styptics, I wish to utter a very strong protest against

the use of that time-honored abomination, Monsell's solution of the subsulphate of iron. It is one of the most powerful of styptics, hence the temptation to use it, but it forms hard, plaster-like coagula, which are either removed with difficulty or remain for some time afterward within the nasal cavity, frequently causing suppuration and sepsis.

As an application to the bleeding-point, when it can be seen, the solid stick or a fifty-per-cent. solution of silver nitrate may be used, either as an adjuvant to mechanical pressure, or alone, if it control the hemorrhage. A few crystals of chromic acid may be used in the same manner. Particular care must be taken in the employment of the latter agent, especially that the blood does not spread it over a large area and cause too extensive cauterization.

The electro-cautery is a most effectual means of arresting hemorrhage. It is, however, not usually accessible when needed. Its use is allowable when applied carefully to the bleeding-point only.

One of the most powerful vasomotor stimulants of the dried extract of suprarenal capsule. This property of vascular contraction makes the remedy a very useful one for the control of nasal hemorrhage. It may be applied to the bleeding surface in the form of the powdered extract; or, better still, as a spray. The solution should be freshly prepared, as it readily decomposes. It can be made in the following manner:

℞ Extract suprarenal capsule.... gr. xx.
Glycerin ..... ʒ j.
Aquæ ..... ʒ iij.

Misce. Macerate for one half hour. Filter and then boil the solution for a few minutes to sterilize it.

The glycerin is added for the purpose of prolonging the period of preservation only, and may be omitted.

A twenty-per-cent. solution of ferropyrin in water is one of the cleanest and best astringent and styptic applications of which I am cognizant. It may be sprayed freely into the nostril without fear of harm. Antipyrin, on account of its contractile effect upon capillary vessels, acts with desiderable efficiency in producing and maintaining an ischemic condition of the nasal mucous membrane. A four-per-cent. aqueous solution may be used for this purpose. Alum is another clean and eligible astringent, which may be applied in solution, dr. 1 to 2 in oz. 4 of water. Finally, peroxide of hydrogen is an hemostatic of considerable value in capillary hemorrhage.

The list of local astringents and styptics which have been employed in epistaxis is a long one. But the ones above enumerated are those I have found, in my experience, to be the best and most reliable. I might also mention another agent of considerable value, namely, cold, which may be applied by means of ice over the nose, or small pieces introduced within the nostril; or by instillation of ice-water.

If attacks of bleeding from the nose are at all frequent, considerable blood may be lost in the aggregate, even though the hemorrhage be rather insignificant at each recurrence. It is, therefore, of importance, if the cause of bleeding be related to some morbid condition within the nose, that steps be taken in due time to remove the abnormality, if possible. The limits of this paper, however, will not admit of a consideration of the methods best adapted to the accomplishment of this object.

MEDICAL PROGRESS.

Fallacies of Therapeutics.—Traditions of the past often give false reputations to drugs and it is with difficulty that the medical profession is induced to give up a time-honored remedy even when proven to be inert. G. L. Peabody (*Med. Rec.*, Mch. 30, 1901) reviews a number of the ordinary mistaken ideas in regard to therapeutics. The action of bitters in whetting the appetite is probably largely, if not entirely, due to the alcohol contained in the vehicle used. The idea that a person is temperate in the use of alcohol because he never has been drunk is a serious mistake some times made by the physician, for it is the steady moderate drinker who first shows the degenerative evidences in his heart, arteries, stomach, liver and kidneys. Boric acid has enjoyed a very variable career having been used for more than a hundred years as a common internal remedy. As an antiseptic it has very little power, being useless to disinfect wounds, hands or instruments. In deep wounds where sublimate and carbolic are changed by contact with the tissues, strong solutions of boric acid are often very efficacious. To control hemorrhage indirectly through the circulation, tannic acid is valueless, for it is always changed into an inert albuminata before being absorbed. Ergot causes a rise in pulmonary blood pressure, but is frequently given to control hemorrhage. Potassium iodide has been most recklessly given, probably because our knowledge of its action is so uncertain. Outside of its action in specific troubles and in lowering arterial tension its field of usefulness is probably not very wide. Creosote, so freely and frequently given in tubercular conditions of the lung, probably exerts no other influence than to improve intestinal digestion and thus benefit nutrition. In the matter of gaseous disinfection most substances have so little penetrating power that they are comparatively useless. Formaldehyd is the best. Scrubbing with antiseptics, or even rubbing the surfaces with bread crumbs, is doubtless more efficacious.

Local Aural, Nasal and Buccal Anesthesia. A. A. Gray (*Lancet*, Mch. 9, 1901) states that as a means of avoiding cocaine intoxication, of deepening and prolonging the anesthesia and

of facilitating general operative rapidity and convenience, he has found the following procedure very useful. A twenty-per-cent. solution of cocaine hydrochlorate is made in rectified spirit and a twenty-per-cent. suspension of beta-eucaine in anilin oil. In the latter about one-half of the eucaine settles to the bottom, necessitating shaking well before using. After preparing the field for application ten drops of each solution are taken, mixed and well shaken. The resulting turbid, milky solution soon clears up, and contains ten per cent. each of cocaine and beta-eucaine and fifty per cent. each of rectified spirit and anilin. In the nose the mixture is applied on a pledget of cotton and rubbed in as well. In the ear a few drops may be instilled into the canal or, better, gauze soaked in it may be placed over the field through a speculum. In the mouth and pharynx the rubbing or painting on is all that is necessary. There are two difficulties—first, in the nose, the solution at first burns considerably; second, in children, the dose must be modified. A good rule is to use a total of twenty drops of the mixture for adults and in proportion to that amount for children. Its acme of activity is present within about seven minutes.

Indicanuria and Oxaluria, and Gastro-Intestinal Fermentation.—J. A. Wesener (*Jour. Am. Med. Assoc.*, April 6, 1901) discusses the relation of indicanuria and oxaluria to gastro-intestinal fermentation very thoroughly and cites the opinions of numerous investigators as to the meaning and importance of the presence of indican and oxalic acid in the urine.. He gives in detail the method of determining indican in the urine, and also the method of determining the presence of oxalic acid. Wesener has arrived at the following conclusions: (1) Traces of oxalates are found normally in the urine, having been taken in with the food; (2) oxalate crystals usually denote gastro-intestinal fermentation. Food rich in oxalates must be excluded; (3) abundance of oxalate crystals does not signify high acid percentage, because in addition there may be oxalate of lime in solution; (4) indican is often, but not necessarily, associated with oxalate crystals; (5) hyperacidity on a meat diet contributes to putrefaction, whether due to excess of hydrochloric acids or acids of fermentation; (6) in certain disturbances of the gastro-intestinal tract due to excess of hydrochloric acid or to excess of fatty acids, in which there is fermentation, indican and oxalic acid are increased; (7) the symptoms of oxalic acid diathesis associated with indicanuria are not due to the oxalic acid nor to the indol, but to other products formed in the process of fermentation, and therefore the oxaluria and indicanuria are valuable as indicative of a putrefaction, to which the symptoms are to be referred. The study of oxaluria and indicanuria holds open a rich field for investigation. In the intestines there are various poisonous bodies produced directly associated with the formation of oxalic acid and the aromtics. These, when better understood, will lead to new ideas, thereby giving one a better understanding of chronic disease such as rheumatism, gout, etc.

New Method of Treating Fractures.—Leonard F. Hatch (*Bost. Med. Surg. Jour.*, March 28, 1901) describes a new method for treating fractures of all kinds, based upon modern surgery. The principles upon which he has based his treatment are to convert all compound fractures into simple ones, and to operate on simple fractures, making them compound, and then apply the first principle, making them simple. Fractures treated by this operative method are practically free from all pain, as both the sharp spiculæ of bone sticking into the soft parts and the swelling are avoided by the operation. In a compound fracture the wound is simply enlarged, while in simple fracture there is a point of selection for the incision. There must be the most perfect antiseptic preparation. Elevate the limb and apply a rubber constrictor. Fit a sterile posterior and anterior splint of any suitable material. The points of selection for incision are for the tibia along the crest, for the femur along the outer side of the thigh, for the radius behind the supinator longus, for the ulna along the ulna side of the arm where the bone is most superficial, for the humerus along the outer side of the arm. A good free incision should be made, all clots and *débris*, such as shreds of tissue and loose pieces of bone, should be washed out, and all bleeding points tied. Be sure that the wound is dry, and see that coaptation is perfect. Apply one of the splints before closing the wound, close the wound with catgut sutures without drainage, lay a thin pad of gauze over wound and apply the other splint and bandage quite firmly. Remove dressing on seventh or eighth day and apply ambulatory splint or plaster cast. Hatch reports in detail fifteen cases illustrating the advantages of this method of treatment, and formulates the following deductions: (1) We should not be deterred from operating on fractures by fear of sepsis, and it certainly is unscientific to adopt a blind way when a better presents; (2) it would be warranted if it did nothing more than to relieve the pain and swelling, which it certainly does; (3) it shortens the repair process about one week; (4) it reduces the chances of deformity and nonunion to a minimum. The writer considers the ambulatory splint the best dressing for fractures of the leg.

Radioscopic Plate Study.—K. Ludloff (*Centralbl. f. Chir.*, 1901, No. 11.) says that for years at the Königsberg Surgical Clinic for the public demonstration and study of radioscopic pictures, the negative has been found advantageous. If the audience is a large one they have used the skiopticon and reduced diaposi-

tives. Very recently the Hirschmann apparatus for the demonstration of the original plate had been most serviceable. Its details are, in brief, a box with a light portable stand, within which a star of electric lamps and several mirror plates cast the light upon a dark plate of glass. Before this rather evenly and diffusely illuminated plate the radioscopic plate is placed in frames. In a dark room, with the light toned down to suit the thickness of the plate, this method brings out many wonderful details. He has found that a sharp first-class opera-glass is a remarkable aid in studying the negatives illuminated in this way, with the observer three to ten meters away. Radiographs of large parts of the body, as pelvis, abdomen, vertebral column, etc., are reviewed as wholes much more easily without being confused by details. In the absence of this special Hirschmann appliance, the negative can be placed in a frame before a window (northern exposure always) and with the aid of curtains a good view can be had. Reduced diapositives can be advantageously studied in the same way with a common reading glass in the ordinary dark finishing room.

Inoperable Cancer.—G. R. Leighton (*Brit. Med. Jour.*, March 16, 1901) states that the treatment of cancer which is beyond the limits of surgical aid is a great problem to the general practitioner and the surgeon alike. He has found in his cases, for example, that the three troublesome symptoms hemorrhage, foul discharge and pain will yield well to the following management. Bleeding is easily commanded by fluid extract of ergot internal and by ergotin hypodermatically. The disgusting foul-smelling discharge is obviated by washings and wet dressings of some antiseptic and deodorant. None is better than carbolic-acid solution, about 1-40 strength. Pain in the early days will decrease or vanish with chloral hydrate and morphine, but these soon loose their influence. Opium in the form of the tincture is by far the most efficacious, permits of unconscious administration and in steadily increasing dose will give the patient hours of continuous respite from pain and refreshing sleep. When the dose begins to be *ounces* by the day, tincture of belladonna is a valuable adjuvant. In one patient of his in two years' treatment by the above plan he controlled all three symptoms, finally giving nearly *300* grains of opium in twenty-four hours.

Benzin in Surgery.—F. Franke (*Centralbl. f. Chir.*, 1901, No. 11.) says that for years in private and hospital practise he has without known disadvantage used benzin as a substitute for ether wherever the latter is used externally. The manifest gains are that benzin is very cheap, is equally active in dissolving off dirt and fat from the skin, does not cause disagreeable chill of the skin by excessively rapid evaporation, will not nauseate the recently-anesthetized patient by its odor, is a very good solvent for rubber plaster, the removal of which is so painful to some patients, does not cause excruciating pain or abrasions and cuts and is no more inflammable than ether. General use of it for such purposes is worthy of the attention of all.

Creosote in Pneumonia.—For several years I. L. Van Zandt (*Med. Rec.*, Mch. 30, 1901) has been using creosote as early as possible in cases of pneumonia and believes that it has almost a specific action in many cases especially those due to the pneumococcus. At first he gave a combination of ammonium salicylate, gr. vijss, creosote gtt j, syrup. 5j, every three hours. Latterly he has used creosote carbonate, grs. vijss, emulsified with acacia or even larger doses every three hours. Within two days the temperature is frequently down to normal with amelioration of symptoms, but if the drug is then discontinued the temperature usually rises again and the symptoms return. Several noted clinicians have reported similar results from the use of this drug, especially when used in the early stage.

Carcinoma Colli Uteri.—O. von Franqué (*Zeitsh. f. Geburtsh. u. Gynack.*, B. 44, H. 2) states that the explanation of the fact that metastases of these growths usually appear in the parametrium beside the cervix earlier than in the body of the uterus lies in the arrangement of the lymph vessels and the direction of the lymph current. The small channels of the portio vaginalis run upward and outward, those of the middle horizontally outward and those of the upper part of the cervix downward and outward to the lateral borders of the cervix. The existence of valves in addition to this arrangement of the trunks as a rule spreads the disease laterally, while it passes upward only by simple contiguity. The bearing of this upon treatment is manifest.

Ether Narcosis.—W. Reinhard (*Centralbl. f. Chir.*, 1901, No. 11.) says that certain of the unfortunate pulmonary sequelæ of ether narcosis, as bronchitis and pneumonia, are attributable to the excessive mucous secretion throughout the respiratory tract. In the Diakonissen-Krankenhause at Kaiserwerth they have found such hypersecretion to be almost habitually prevented by giving atropine sulphate hypodermatically about an hour before the beginning of the anesthetization. In addition to quieting the mucous membranes the drug is a lasting cardio-respiratory stimulant, which only adds to its indication as a prophylactic of postoperative sequelæ. Morphine may or may not be added.

Acute Gastro-Intestinal Paresis.—O. von Herff (*Zeitschr. f. Geburtsh. u. Gynäk.*, B. 44, H. 2, 1901) formulates the management of these severe acute postoperative dilemmas in the following terms. Prophylaxis consists in great care in the preparation and operation of chronic gastric conditions. The vomiting due to the anesthetic must be checked promptly

by any means approved, and best of all by lavage. This same means is of value in the beginning of the actual paralysis. The appropriate use of nutritive and stimulating enemata is very valuable. Faradization of the stomach is excellent. To combat the great thirst, stimulate diuresis and support the circulation, give normal salt solution enemata or better still infusions up to one to one and a half liters in twenty-four hours. Some authorities try the knee-elbow position. The best is the abdominal position with the hips well elevated.

Enteric Fever in Childhood.—Children commonly have an atypical temperature range, usually with step-like ascent in the first week, level but with morning remissions in the second week, and a gradual or sudden fall in the third week. W. L. Stowell (*Archives of Pediatrics*, April, 1901) found apathy, mental dulness, or headache common and epistaxis especially so, though Vogel speaks of it as rare. The compressible and non-resistant pulse are diagnostic before dicrotism or intermittence supervenes. Leucocytes and erythrocytes are both diminished. Tympanites is less frequent than in adults; gurgling at the ileocecal valve is common. One-third of the cases had diarrhea, many had tender large spleen, albuminuria was rare. The complications noted are varicella, parotitis, bronchitis, pneumonia, intestinal hemorrhage (very rare), and perforation. There were three relapses in seventy-seven cases. Give milk diluted with vichy, seltzer, or lime-water, as a diet, and if the fever is high partly peptonize it. If no diarrhea, add bouillon, broths, and meat-juices. Custards, gelatin, and egg beaten in milk may be allowed, also lemonade, iced coffee or cocoa and ice-cream. Supply liberally with water. During the first few days calomel gm. 0.006 (gr. $^1/_{10}$), every hour as a laxative, and salol, as an antiseptic, are indicated, also citrate of magnesia. During the third week strychnine, digitalis, camphor, ammonia or coffee will stimulate the heart. Liquid peptonoids furnish alcohol combined with food elements. A Dover's powder quiets delirium, and older children may have morphine, gm. 0.02 (gr. $^1/_3$), with camphor, gm. 0.03 (gr. $^1/_2$). Baths are not usually well borne, but sponging is good. Chloride of lime, gm. 2.50 (℥viij) in 4 liters (one gallon) of water makes a stock disinfectant of which 30 gms. (℥i) in 4 liters (one gallon) of water may be used for excreta and soiled linen.

Diabetes Mellitus.—In reviewing the early symptoms of diabetes, H. S. Stark (*Med. Rec.*, April 6, 1901) mentions the periodic headaches in obese subjects over thirty-five years of age, extreme and lasting fatigue after a short but violent exercise, and prolonged fatigue after slight exertion. Also slowly failing vision in the aged or quickly failing sight in the young, certain signs referable to the mouth such as acid saliva, receding gums, fissured and extremely reddened tongue should be looked upon as suspicious symptoms. Premature grayness or sexual weakness, diminished patellar reflex, slow healing of wounds and cramps in calves of legs, with muscular weakness, are frequently met with early in this disease. The prognosis depends upon several features. This is the only disease in our nosology in which old age is an advantage. The power of assimilation is extremely important, and permanent intolerance to carbohydrates is very unfavorable, especially when a glycosuria persists despite a rigid antidiabetic diet. An early recognition of the disease is to be desired, and hence routine examinations of urine are suggested. The ability to lead a sedentary life, free from care and worry, is important; the discovery of acetone or diacetic acid in the urine makes the prognosis very grave. Finally, much depends upon the capacity to absorb and assimilate fatty and nitrogenous foods, to the exclusion of carbohydrates. They may all be divided into the mild type, the medium type, and the severe type.

Comparative Pathology of the Jews.—After a thorough investigation of the relation of disease to the Jews and other races, M. Fishberg (*N. Y. Med. Jour.*, March 30 and April 6, 1901) reaches the conclusions that the death-rates of the Jews, at all ages, are comparatively and absolutely lower than those of the people among whom they live. Syphilis and alcoholism, and also diseases due in a great measure to their poisons, are comparatively rare among the Jews. Diabetes is very common, some believing that twenty-five per cent. of all cases occur in Jews. Functional neuroses and psychoses occur frequently among the Jews, but the organic nervous lesions are less common than among non-Jews. Blindness, trachoma and glaucoma are very often seen in members of this race. These peculiarities are not due to any ethnic, "biostatic" or racial characteristics of an anatomical or physiological nature, but have their origin in the past history of the Jews, in their habits of life, and in the fact that syphilis and alcoholism have but rarely been seen among them.

Rectal Feeding.—In numerous throat affections mouth-feeding is not only most distressing to the patient, but also interferes materially with the healing of the diseased parts. In operations upon the mouth or pharynx, in cases of diphtheria or severe laryngitis of children, or in tubercular laryngitis when the passage of food is extremely painful even after cocaine has been freely used, rectal feeding becomes not only comforting to the patient but by far more efficacious in maintaining the nourishment. Of course, it cannot be continued as the sole method of imbibing food for more than two or three weeks. A. C. Bardes (*Med. Rec.*, April 6, 1901) recommends the use of one to six ounces with the addition of ten drops of laudanum in case the rectum is irri-

table. Milk is the chief article employed. There are two processes of preparing, the cold method in which ten grains of pepsin are dissolved in four ounces of water, a pint of milk added and the mixture placed upon ice. When needed heat to 105° F. and inject. In warm process, the food is prepared as above and heated to 115° F. for half an hour, then placed upon ice and heated to 105° F. when needed. An egg, well beaten, may be added.

Ambulatory Typhoid with Perforation.—A peculiar case of a boy, seven years old, sick with typhoid fever of a mild type for one week in whom perforation suddenly occurred is reported by A. A. Berg (*Med. Rec.*, Mch. 23, 1901). He had headaches and general lassitude, but no abdominal pain, the stools were normal and he was not confined to bed during the week's illness. On day of the perforation he had violent cramps in lower abdomen, especially right iliac fossa. He had several chills followed by fever during the day and vomited once. There was no collapse. The temperature was 103° F.; pulse 136. Spleen and liver appeared normal, but there was much distention. Operation disclosed a seropurulent fluid and injected peritoneum, normal appendix and a small perforation of an enlarged Peyer's patch. The child made a good recovery, the temperature ranging from 100° to 104° F. during the next nine days. The stools were not typhoidal, the diazo remained negative, but a positive Widal was obtained on the nineteenth day. In speaking of the diagnosis and treatment of this condition the author insists on the necessity of making an early diagnosis. The symptoms of the preperforative stage due to the localized peritonitis are: (1) Local rigidity of the abdominal wall; (2) usually an increased leucocytosis; (3) local pain and tenderness; (4) possibly nausea and vomiting; (5) possibly increased pulse-rate and temperature. The first two are by far the most important and frequent examinations should be made to detect them. The evidences that a perforation has occurred are due entirely to the intestinal extravasation and may therefore be insignificant or of an alarming character. When severe they are the symptoms of shock—collapse, fall of temperature, cold clammy skin and rapid feeble pulse. As the peritonitis progresses Cushing has shown that the leucocytosis diminishes while the local signs of peritonitis increase. It is therefore very essential to detect the symptoms of the preperforative stage and although these do not indicate an operation, the subsequent appearance of shock or a decreasing leucocytosis with increasing abdominal rigidity urgently demand surgical interference.

Chronic Gonorrhea and Marriage.—Some authorities go so far as to say that since it can never be positively proven that the gonococci have entirely disappeared, consent to marriage should never be given, but since this would condemn nearly ninety per cent. of all male persons to celibacy the rule becomes most impracticable. L. Weiss (*Med. Rec.*, Mch. 23, 1901) believes that the decision should rest entirely on careful repeated examinations of the threads and the exudate expressed from the seminal vesicles and prostate. When the gonococci have entirely disappeared from these an irritative injection of a two-per-cent. silver nitrate solution or a 1-10,000 bichloride solution is made to induce a mild urethritis and cause the exudation of pus, epithelial cells and the gonococci which lurk in the epithelial cells or deeper structures. Not only microscopical examinations should be made, but cultures should be taken and both methylene blue and Gram's staining methods applied to the colonies grown. When after repeated examinations the presence of gonococci cannot be demonstrated, permission to marry should be given.

Vaccination.—H. Palm (*Arch. f. Gynack.*, B. 62, H. 2) has observed the phenomena of vaccination among pregnant and nursing women and newly-born children, and concludes as follows: (1) Inoculation of the women at least during the last four months of pregnancy is harmful for neither mother nor child. The very fatal ravages of smallpox among the pregnant make vaccination of them peremptory; (2) such successful inoculation of the mother, even late in her pregnancy, does not protect the child; (3) it does occasionally happen that a child of such a mother will be resistant partly or totally to vaccination; (4) vaccination is well-borne by the youngest children, even those a day old, and even premature whether artificially or naturally fed; (5) vaccination of the newly-born is always peremptory in the presence of a smallpox epidemic; (6) habitual inoculation of such infants is not justifiable, because they are more susceptible to the accidents and bad-effects which occur among adults.

Tropical Dysenteries.—After considerable experience with our armies in the South and the Far East, S. M. Long (*N. Y. Med. Jour.*, Mch. 30, 1901) concludes that only a few drugs have proven to be of any decided benefit. Although there are several types of the disease, the usual case of acute dysentery should first be given calomel in small doses to thoroughly clear the bowel. Ipecac is an excellent drug if given properly. The patient should be put to bed, and from fifteen to twenty drops of tincture of opium administered. Soon afterward put ice-bag on head, mustard paste on stomach, give a hypodermic of one-quarter grain of opium, and administer forty grains of ipecac by mouth. Nothing should be swallowed, not even saliva, and the patient should be kept quiet for four hours. A second dose may be necessary and in this way nearly eighty per cent. of cases can be cured. The subnitrate is the best preparation of bismuth

and this should be given in large doses, thirty or forty grains, and its action is enhanced by the addition of five grains or Dover's powder. Enemata are of great value in some cases. A soap-suds enema should be given first and then a hot-water irrigation medicated with silver nitrate or chloride of iron is given by means of a soft rubber tube. Normal salt-solution enemata, laudanum, and starch-water are also good.

Etiology of Cirrhosis of Liver.—With the intention of proving the action of poisons of liver cells, A. Marckwald (*Münch. med. Woch.*, Mch. 26, 1901) fed a number of frogs, with small, but gradually increasing doses of antipyrin. The organs reacted alike in all animals and three pathological stages could be observed: total destruction, beginning degeneration and transitions between both. Strangely, however, no true cirrhotic processes were found since in no place were the destroyed cells replaced by connective tissue. This the author ascribes to the fact that frogs in confinement do not spontaneously take nourishment and that thus reactive power on part of the tissues is impossible. On feeding the animals with meat quite different results were obtained. In places where there was much breaking down of liver-cells a granulation-tissue, consisting of intensely staining round cells had made its appearance. There is little doubt that in man a similar process goes on in cirrhosis of the liver and that destruction of liver-cells is the first and primary change.

Mixed Cirrhosis of Liver.—H. Ullmann (*Münch. med. Woch.*, Mch. 26, 1901) points out that it often is impossible to classify all cases into either atrophic or hypertrophic and that one often meets with large livers giving symptoms of the atrophic variety. So also in the case which the author cites where the liver reached to near the umbilicus and where enlarged spleen, ascites, distended abdominal veins and jaundice were present. The course of the disease here was very rapid, the patient dying several weeks after the onset of the symptoms. Only alcoholism could be found as cause. Microscopically a well-marked increase of connective tissue which stood in no definite relation to the liver-lobules could be demonstrated. The liver-cells themselves were fairly well preserved.

Treatment of Tuberculous Osteo-arthritis.—C. Trunecek (*Klin. therap. Woch.*, Mch. 31, 1901) recommends the following procedure where fistulæ are present. The granulations about the fistulous tracts are removed and the adjoining skin protected with vaseline. The cavities in the bone or joint are then washed out with a solution containing all the salts of the blood-serum in their normal proportion, but in a concentration of 20 per cent. A caustic action results without introducing any foreign material into the organism. A Priessnitz is applied after the lavage to reduce the inflammation which follows. The results are excellent, especially if the lavage is repeated several times at intervals of two weeks.

Charcoal and the Tubercle Bacillus.—It is a well-known fact that those subjected to the dust of carbon in any form are much less liable to suffer from tuberculosis than where other forms of dust are inhaled. To ascertain whether the various forms of carbon have any inhibitory action upon the development of the tubercle bacillus, J. Papasotiriu (*Münch. med. Woch.*, Mch. 26, 1901) grew them upon glycerin-carbon-agar with the result that they flourished just as well as before the addition of the carbon. The above fact must therefore find its explanation in a different way.

On Subcutaneous Injections of Paraffine.—The hypodermic use of paraffine has recently been recommended for cosmetic purposes to replace extirpated breasts, removed testicles, etc. H. Meyer (*Münch. med. Woch.*, Mar. 12, 1901) warns against the dangers connected with this procedure since the paraffine will slowly leave the original site of injection and will tend to eventually occlude the lymph and tissue-spaces with resulting disturbances of nutrition. The same may possibly hold true for the oil-injections employed for nutritive purposes.

Treatment of Acne Pustulosa.—Nitric acid, turpentine, a bundle of wooden toothpicks, blotting-paper and vaseline, together with some iron-strychnine-quinine pills and cod-liver oil, is the outfit with which H. L. Jones (*British Med. Jour.*, Mch. 2, 1901) successfully treats the worst cases of acne pustulosa. The pimples' base is smeared with vaseline, a toothpick, dipped in the acid and hurriedly dried on the blotter, is thrust into its depths, twisted three or four times and removed. If one the face, not more than six or eight should be treated at a sitting; if on the neck and shoulders, upward of twenty. The patient must be told that it will take from ten to twelve sittings in a bad case, and, particularly, that if a single pustule be left remaining the disease will surely return.

The Anopheles Campaign.—H. E. Durham, writing from Parà (*British Med. Jour.*, Mch. 2, 1901) has several interesting suggestions as to the ultimate extinction of malaria. He notes that throughout the southern countries there is but one time in which to make profitable use of chemical culicicidal agents in the marshy districts, *i.e.*, immediately before the rainy season. This conclusion, together with the belief that this mode of attacking the *Anopheles* is decidedly Utopian, he has gathered from experiments with a series of stagnant pools in the vicinity of Parà. He also concludes that Koch's vision of a universal cinchonization of communities would avail little, since quinine is lethal to some forms only, *i.e.*, the crescents. He

feels that if the parasite is to be successfully attacked *via* the human system, arsenic, which destroys the reproductive form, should be given for the protection of the community, while quinine must be restricted to the relief of the individual. It thus appears that, so far, man's best weapon against the *Anopheles* is drainage.

THERAPEUTIC HINTS.

Diphtheria.—With the exception of cleansing sprays of 6 per cent. boric acid solution, listerine and water, or salt and water, local applications are mostly unnecessary and therefore bad, writes Chas. C. Gidney (*Pediatrics*, Mch. 15, 1901). In mild cases seen early, 600 to 1,000 units of antitoxin injected between the scapulæ or into the cellular tissue of abdomen or thigh, will suffice. In cases however of extensive membrane, 4,000 to 6,000 units should be injected at once, and perhaps an additional 2,000 to 3,000 units in the next day or two. Overdoses are harmless, as much as 12,000 units having been repeatedly used in the Brisbane Children's Hospital. When the pulse indicates it strychnine, digitalis, or alcohol may be of service.

Gargles.—Much has been written about the futility of gargles, but H. Lavrand believes that the muscular tension of gargling is of some value in itself, and that gargles can easily be made to reach the posterior pharyngeal wall. He makes his patients take a mouthful of liquid, throw the head backward, open the mouth as widely as possible, and in this position attempt to exhale the breath. Then on quickly lowering the head some of the water is extruded by the nose, thus showing that it must have been in the pharynx. The method may be used to medicate nose, mouth or pharynx. In the above position a little liquid dropped on the tongue will run down into the larynx, but does not pass the vocal cords. The epiglottis, arytenoid bodies and vocal cords may thus be medicated. The author cites numerous experiments of painting the pharynx with methylene blue and gargling with water, with glycerite of starch and gargling with iodine solution, with tincture of iron and gargling with sodium salicylate solution, with glycerin solution of tannic acid and gargling with ferric perchloride, etc., all of which show that the posterior pharyngeal wall is reached by the gargling solution when the patient throws the head back and opens the mouth wide.—*Jour. des Sciences Méd. de Lille*, Mch. 30, 1901.

Typhoid Fever.—R. Romme (*La Presse Méd.*, Mch. 20, 1901) finds that quinine and the bath are the favorite remedies for typhoid. Glénard uses the full Brand system of bathing. Comby, Guinon, Marfan, and Aussi give the first bath at 95° to 85° F., and in successive baths lower the temperature till it reaches 75° or 70° F. Variot gives tepid baths, and Netter warm baths like those Rénaud advises in bronchopneumonia. Among Germans, Binz and W. Erb have recently independently made pleas in favor of the use of quinine. Erb's treatment consists of attention to diet and hygiene, tepid baths progressively cooled, and quinine, gm. 1.0 to 2.0 (gr. xv-xxx), at night when the fever is at its height. Erb has abandoned the use of antipyrin, phenacetin, lactophenin, salophen, etc. He believes that quinine is not only antipyretic, but that it acts favorably on the course of the disease, shortening its duration. Binz prefers the hydrochlorate of quinine, as it is much more soluble.

Chloretone as Analgesic.—E. H. Siter (*Therapeutic Gazette*, March 15, 1901) has used chloretone in solution as a local anesthetic with extremely poor results, but in the form of a dusting-powder he has found it to mitigate or entirely allay the pain of granulating wounds. It neither hastens nor delays granulation and may be used with any dusting-powder, such as boric acid.

Guaiacol in Skin Tuberculosis.—A mixture of equal parts of guaiacol and olive oil is painted on the ulcerated area three times a day, after the crusts have been removed, and all exuberant granulations destroyed by a ten-per-cent. solution of lactic acid.—*Jour. de Méd. de Bordeaux*, Mch. 31, 1901.

Erysipelas.—The disease is self-limited and most cases get well without any internal medication. According to Osler the diet should be nutritious and light; chloral or bromides may be given for restlessness, delirium, or insomnia, and if these fail, opium. If the fever is high the patient may be sponged or bathed, or given antipyrin or acetanilid. The tincture of ferric chloride has been much given in dose of gm. 2.0-4.0 (℥ss-i), every 3 or 4 hours, with questionable benefit. Locally, a two-per-cent. solution of carbolic, or solutions of the bichloride or biniodide of mercury may be injected beyond the border of the spreading area. Ichthyol is at present much used. Perhaps as good an application as any is cold water.—*Practice of Medicine.*

Sweets.—Their action on the stomach and intestines, write Van Valzah and Nisbet, is one of excitation of secretion and peristalsis. Large quantities are hydragogue, the secretion being poor in hydrochloric acid and ferments. In disease their digestibility is greatly modified and their easy fermentation constitutes a serious objection to their employment. Concentrated solutions of sugar congeal or may even inflame the mucosa. In the diseases of the stomach with excessive secretion all sweets must be prohibited; but if the digestive tube is sweet, the motor functions efficient, and the stomach not morbidly sensitive or inflamed, sweets may be permitted. In adenasthenia gastrica they may be beneficial. Milk-sugar is very nutritious, excites secretion but little when given well diluted and in small quantity, and is a valuable laxative food.—*Diseases of the Stomach.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, APRIL 20, 1901.

ROUTINE DOUCHING IN OBSTETRICS.

Since Semmelweis showed how greatly the mortality from puerperal infection might be reduced by simply washing the operator's hands before delivery, much attention has been devoted to methods for still further diminishing the number of infected cases. With this object in view routine vaginal douching before labor has been advocated by many obstetricians. In the year 1887 Gönner announced that the vaginal secretion of pregnant women examined by him did not contain the pathogenic bacteria which were usually found in puerperal infections, and that for this reason the use of vaginal douches before labor for the prevention of auto-infection was unnecessary. Since that time the advisability of routine douching before and after delivery has been frequently discussed.

The statistics advanced by those in favor of routine douching, as well as those presented by the opponents of this procedure, are of uncertain value. This is due largely to the diminution of the number of cases of infection in the maternity hospitals, by reason of the many improvements in aseptic technic, such as the restriction of frequent internal examinations, and careful disinfection of the hands. This small proportion of infected cases affords poor grounds for estimation of the results of antepartum douching, as some of the cases infected are doubtless due to individual errors in technic and so prove nothing in regard to the value of douches.

Certain observers have discovered pathogenic micro-organisms in the normal vagina and for this reason advocate prophylactic douching. Others hold that the vaginal secretion possesses bactericidal qualities. These are attributed by Döderlein to its acid reaction produced by the vaginal bacillus which bears his name. The experiments of Krönig show that the vagina takes longer to eliminate pathogenic bacteria artificially introduced, when douches are employed; and other investigators have found that douching, with or without antiseptic solutions, usually fails to remove such organisms.

The recent bacteriological researches of A. Wadsworth (*American Journal of Obstetrics*, April) have led him to condemn routine antepartum or postpartum douching. His technic was such as to exclude all possibility of contamination of the uterine and vaginal secretions, and both cultures and staining methods were employed. He found that it was exceptional that pathological bacteria persisted in the vaginal secretion through pregnancy and labor, but that if they were present the lochia favored their growth, and energetic antisepsis after labor was necessary. Cultures from several cases in one of the best of New York's maternity hospitals demonstrated the persistence of streptococci in the vagina after repeated douching with a 1-5,000 solution of bichloride. He considers as requisite points that the disinfecting solution be brought into contact with all bacteria by distending the folds of the vagina, and that it be of sufficient strength to kill the micro-organisms without, however, injuring the vaginal wall. The douche, as ordinarily given, merely removes the protective resources of the vagina. Wadsworth's cultures confirmed the statement that the uterine cavity is usually germ-free. He emphasizes the necessity of differential diagnosis between sapremia and septic conditions, since intrauterine douching after labor is strongly indicated for the removal of the abnormal contents

of the uterus in the former class, while in septic conditions it is likely to aid in disseminating the process unless the uterine sinuses have been closed by granulation tissue. The rule which he lays down is that bacteriological examination of the cavity of the uterus should always precede an intra-uterine douche and such an examination should be made early, since, if a radical operation is required, an early determination of this point is of great importance in regard to its prognosis.

Reviewing the results of Wadsworth's observations as well as those of others, one cannot fail to note that antepartum douches frequently fail to remove pathogenic bacteria when they are present; that they destroy the natural protection of the vagina, whether this be its secretion as a whole or the vaginal bacillus; that they are liable to cause slight injuries to the vaginal wall and so furnish points for the entrance of infection, or at least, by removing the lubricant of the vagina to make labor more difficult and thus favor such vaginal traumatism; and, finally, that pathogenic bacteria may be introduced by these manipulations. For these reasons, and on account of the danger of dissemination of sepsis by intrauterine douching while the uterine sinuses are closed only by infected blood-clots, one must in general agree with Wadsworth's conclusion; that "the routine management of cases should be freed as far as possible from all procedures which interfere with the natural resources of the body; for these, in the vast majority of cases, are sufficient protection against the invasion of pathogenic bacteria. In the few exceptional cases requiring interference this should be determined and directed by the bacterial examination."

This statement seems open, however, to slight modification. No one will deny that after manipulations which require the intimate contact of the hand with the interior surface of the uterus, as in manual extraction of retained secundines, it is wise to give immediately a bichloride douche for the purpose of flushing out any pathogenic bacteria which may have been introduced, before they have an opportunity to become attached to the uterine wall. Such a bacteriological examination as Wadsworth advises is obviously beyond the reach of the attending physician in a large proportion of cases in private practice, and in these the indication for douching must necessarily be derived from careful exclusion of all other causes of fever, with the presence of local symptoms. Whether the uterine condition is one of sapremia or of sepsis must, in such a case, be determined by the judgment of the physician, aided by the history of the labor and the probability of infection before or during labor as opposed to retention of secundines. As a general rule avoid douching in obstetrics unless it is particularly indicated.

DIABETES AND THE PANCREAS.

Embedded in the substance of the pancreas are the peculiar bodies described by P. Langerhans and usually designated islands of Langerhans. They are composed of polygonal cells arranged in irregular columns, between which are wide tortuous anastomosing capillaries. The lumen of the ducts of the secreting acini of the pancreas does not penetrate the cells in these islands and it is therefore inferred that they are not concerned in the formation of the pancreatic juice. It is interesting, moreover, to note that these bodies resemble other ductless structures, notably the parathyroid and carotid glands and in some respects the suprarenal, pituitary and thyroid bodies.

Such is the general introductory description of these bodies as given by Dr. Eugene L. Opie in a recent study on the "Relation of Diabetes Mellitus to Lesions of the Pancreas" (*Journal of Experimental Medicine*, March 25, 1901).

The histology of these bodies has suggested to physiologists that perhaps the pancreas also had an internal secretion which might be found to have some relation to carbohydrate metabolism, and certain experiments by Ssobolew have seemed to bear out this hypothesis. Dr. Opie's researches, from the pathological side, tend further to strengthen the theory. He characterizes two types of pancreatitis, one an interlobular form, in which with other changes the islands of Langerhans are only secondarily implicated and a second, or interacinar pancreatitis, in which these structures suffer with the other elements of the gland. With the former type, diabetes is not a common accompaniment; with the second, however, he believes that it is, and an interesting case is described in which these islands have undergone complete hyaline degeneration. The clinical history was accompanied with marked symptoms of diabetes mellitus. This case, with some others previously reported, calls

attention to this peculiar type of lesion, and while it is unquestionably true that impaired pancreatic function is not the only cause of diabetes, in fact, pancreatic disease is absent in many frank cases of this affection, yet the author concludes that destruction of this portion of the organ will cause the disease.

As he concludes, "Destruction of the pancreas in animals, and in man, is accompanied by diabetes; in the present case destruction of the islands of Langerhans has been accompanied by this disease. Since diabetes is absent when, as the result of duct obstruction, the secreting portion of the gland undergoes great alteration, although the islands are spared, the conclusion is justified that it is those structures which influence carbohydrate metabolism. What has been learned concerning the relation of the pancreas to diabetes is the relation of the islands of Langerhans to this disease."

APROPOS OF THE CITY CHARTER AND BELLEVUE.

The members of the committee appointed by the Medical Board of the City Hospital to take action in regard to the amended city charter so far as it affects Bellevue and the allied hospitals object to the proposed change of vesting the authority of management in a board of seven trustees, instead of in the one commissioner.

Reforms, in New York are about as permanent as street improvements; no sooner does the commotion, up-tearing and relaying pave a sightly thoroughfare, than the whole thing must be ripped up and done over again. Bellevue reforms have been stirred up before and at the change of administration have relapsed into their former condition. If anything permanent is to be accomplished it must be by organizing the hospital administration on lines that are wholly outside of politics; and to accomplish this we state once more what we have already emphatically repeated that if Bellevue is to be placed in the same irreproachable category as other hospitals it should be managed as they are, by an unsalaried board of trustees; trustees who shall be chosen from among the powerful and influential men of the city who will give as disinterested service to the city's sick, as do the other able men who serve upon the board of trustees of the great private hospitals.

Drs. Edward S. Peck, C. L. Gibson, Charles C. Ransom, Robert H. M. Dawbarn, Alfred N. Strouse, and Nathaniel Bowditch Potter who compose this committee are rather vague in their objections, if we are to judge by press notices. They think that the complex methods of making nominations for the positions of trustees are no guarantee of the occurrence of a state of harmony or common interest in caring for the sick and that there would be opportunity for the furtherance of special and individual purpose. We wish to remind the committee that Bellevue has been through a good many reforms, and is not much better off for them; that as soon as the present commissioner retires, the hospital will be at the mercy of whatever politics may throw its way; that the public will feel that enough attention has been bestowed upon its betterment, and will turn wearily away when the same process of ripping up again becomes necessary, and that now is the great opportunity, once and for all, to put Bellevue and the allied hospitals under a different management.

It may cost a little more to readjust the relations but it will be money for which value will be received; and so long as the money goes directly to the city's poor and not to its politicians, we do not see why the committee should be so chary about the outlay. None of their excuses about the possible friction, the possible personal aggrandizement, and the possible extra expense should have weight in comparison with the actual state of affairs that has been tolerated in spite of all efforts to modify it during the last twenty years.

ECHOES AND NEWS.

NEW YORK.

Brooklyn Pathological Society.—At the last regular meeting of this Society, held April 11, Dr Clarence Hyde read a paper on "Urethral Caruncle" and Dr. J. S. White contributed a paper on the "Diognosis of Bone Disease by Means of the X-Rays." Drs. James Sears Waterman, Walter C. Wood and William B. Brinsmade presented interesting specimens.

Coroner's Physician.—Dr. Edward T. Higgins of 818 East 147th street has been appointed a Coroners' physician to succeed Dr. Edward J. Donlin, who was recently made a police surgeon.

Dr. Brooks, Zoo Pathologist.—By resolution of the Executive Committee of the New York Zoölogical Society, Dr. Harlow Brooks has been appointed pathologist to the New York Zoölogical Park. This is considered an important step in the extension of original scientific work, for the park collections furnish a splendid field for the study of comparative

pathology. A laboratory will be fitted up in the temporary administration building, now approaching completion, and this will be assigned to Dr. Brooks. In creating the position of pathologist, the Society has defined his duties as follows: "To make regular visits to the park, to examine into the hygienic condition of the animals, and to recommend such treatment and to make such autopsies and microscopic studies as will tend to advance our knowledge of the prevention and treatment of the diseases peculiar to animals in captivity."

Physical Education.—The twelfth annual meeting of the American Association for the Advancement of Physical Education was held April 18, 19 and 20, 1901. Physical training in the public schools was shown by visitation to several of the gymnasia in the schools of the boroughs of Manhattan and Brooklyn. The gymnasium of Columbia University, the Physical Development Institute, North American Gymnastic Union and the Young Men's Christian Association were also visited. The papers read in the Hall of the Board of Education were interesting and profitable. Physical examination, training and the value of athletics were well discussed. In the Section on Elementary Schools, the questions of hygienic school desks, hygienic instruction, children's games, etc., were among the topics treated. Psychology and psychological tests were made the subject of papers and discussions on Friday morning at Columbia University. These were followed by a number of valuable hygienic studies relative to metabolism and muscular exercise. The effects on blood pressure, the blood composition, influence of posture on respiration, etc., were among the more important papers.

Manhattan Dermatological Society.—A regular meeting of the Society was held on Friday evening, April 5th, at the residence of Dr. Wm. S. Gottheil. Dr. Geyser presented an extensive lupus vulgaris of the face successfully treated by the Roentgen rays. The right side showed a smooth, shining cicatrix, the left a superficial burn and an X-ray alopecia. Each sitting lasts from seven to ten minutes and is followed by a static spray which is said to "deaden" the pain. Fourteen cases have thus far been treated by him, with very fair results and no ill effects. This method is superior to Finsen's phototheraphy.

Dr. Gottheil presented a boy of ten years with a congenital growth under the right axilla, which consisted of very dark tuberous excrescences. There were a few isolated patches to the outside and a row of similar lesions along the inner side of the forearm. Opinion as to the diagnosis were asked. Dr. L. Weiss considered it a case of acanthosis nigricans. The region of the axilla was characteristic. Dr. J. Sobel would call it nævus linearis verrucusus. The linear distribution on the forearm corroborates the diagnosis. Dr. Gottheil considers it nævus unius latetis or nævus papillomatosus. Dr. J. Sobel presented two cases of pityriasis rosea in children of eight and twelve years respectively. Both showed lesions on the face, and complained of severe pruritus. The lesions take the characteristic mahogany color when painted with Lugol's solution (Allen's test).

Dr. Martus presented a girl, fourteen years of age, with a chancre of the labium and a generalized papulo-squamous-pustular syphiloderm. Sexual intercourse was admitted. Iritis, adenopathy and mucous patches existed.

Dr. Ludwig Weiss demonstrated the development of the molluscum fibrosum in a patient with multiple lesions. Some were more tangible than visible; other lesions were large, others small, some sessile, some pedunculated. A few were soft. Dr. Gottheil said the soft ones suggested an angiomatous element. Dr. Ochs remarked that in a similar case of his he had found Asiatic pill very efficient. Dr. Gottheil presented two patients, one with a positive, the other with a probable disseminated sarcoma cutis. The latter may be syphilis. Dr. Sobel showed a patient with a diffuse chrysarobin dermatitis following the use of a five-per-cent. ointment for psoriasis. Dr. Gottheil demonstrated the use of an elaborate apparatus for the Finsen treatment of dermatological lesions. Dr. Geyser presented a lupus vulgaris of the neck which had been subjected to one sitting of the X-ray. Dr. Gottheil showed a patient with a gummatous deposit in the sternocleidomastoid muscle and the clavicle.

Academy of Medicine.—The Section on Laryngology and Rhinology will meet Wednesday, April 24th. Dr. Clarence C. Rice will read a paper on "The Importance of Preventing Chronic Suppurating Ethmoid Disease by Prompt Local Treatment," and Dr. Beaman Douglass will read a paper on "Nasal Conditions Observed in the Aged."

For the Section on Obstetrics and Gynecology to be held Thursday, April 25th, the following papers are announced: "Symphyseotomy" by Dr. E. V. Ayers; "Cæsarian Section" by Dr. E. B. Cragin: "Dilatation of the Cervix" by Dr. H. J. Garrigues; "Axis-Traction Forceps" by Dr. E. H. Grandin, and "Version: Indications, Limitations and Technic" by Dr. S. Marx. A general discussion by Drs. R. A. Murray, H. C. Coe, Charles Jewett, H. J. Boldt, G. W. Jarman and others will follow.

Hospital Staff Appointments.—Among some of the successful candidates for hospital internships at the recent examinations are Dr. P. W. Bill, Methodist Episcopal Hospital; Drs. F. G. Hodgson and Condit, St. Luke's; Drs. S. V. Whitbeck and D. B. Deming, Roosevelt.

PHILADELPHIA.

Is Erysipelas Contagious?—A difference of opinion regarding this question is barring a Germantown domestic from the hospitals of

this city, application to nearly all of which having been made by her physician. The general hospitals refuse the case because the disease is contagious. The authorities of the municipal hospital refuse the case because that hospital is for the treatment of contagious diseases only, the rules thus making erysipelas one of the diseases which cannot be treated there. The physician of the patient states that he is not prepared to say that erysipelas cases should be placed in surgical wards, but when in their proper place, the medical wards, there can be no possibility of contagion.

Tributes to the Memory of Dr. Pepper.—At the April meeting of the College of Physicians Dr. James Tyson read a memoir of the late Dr. William Pepper. The recital of what that remarkable man accomplished as a teacher, practitioner, organizer, founder, author, and as an executive, fills one with amazement. In addition to these points Dr. Tyson paid an eloquent tribute to Dr. Pepper as a colleague and a friend. A portrait of Dr. Pepper was presented to the American Philosophical Society April 12th. Dr. Horace Howard Furness, who presented the portrait on behalf of a number of the members of the Society, said in part: "By one noteworthy element in Dr. Pepper's temperament I was always impressed, and that was a sense of proportion. He had the faculty of differentiating values. His perspective was always true. At a glance he distinguished the permanent and the transitory. Therefore it is that the institutions with which he was connected or which he guided will for many a year to come follow out the lines which he, in his far-seeing wisdom, laid down. Ambition is proverbially selfish, and that he was ambitious we all know. But herein was what was almost his crowning quality. His ambition was never for himself. If he was exacting and determined in the pursuit of his ambition, it was not for his own ends. His ambition was set in the attainment of loftier planes for the institutions for which he toiled and planned. To the reflex effect upon himself or his fortunes of any course which he deemed of moment, I think he never gave a single thought."

Amend the Rules.—Daily newspapers so often make a muddle of matters medical by misquoting, using wrong terms, and becoming sensational in regard to items of news that we desire to give the *North American* credit for a strongly put, but appropriate editorial in the issue of April 15th. The case in question was that of a young colored woman who found her way to the Presbyterian Hospital just as she was to give birth to a child. The staff refused to admit her because they handle no maternity cases. Removed by a patrol wagon the woman was delivered of the child before the Philadelphia Hospital could be reached. The authorities of the first named institution upheld the action of the staff. The editorial is as follows: "Those managers of the Presbyterian Hospital make a grave mistake who attempt to justify the turning away from the doors of the institution of a woman in woman's last extremity. It was an inhumane, an un-Christian act. It is known that the Presbyterian is not a maternity hospital, and that to take in such patients under regular conditions is against the rules. But no hospital should have rules of a kind that will compel its staff to refuse emergency aid to a human being. We trust that the managers of the Presbyterian Hospital, instead of seeking excuses in palliation of an act which has shocked the humanity of the community, will be sufficiently wise to instruct the staff to be more anxious hereafter to behave mercifully in a crisis than to apply rules. In that way the managers may in part atone for the outrage of which a friendless and penniless and agonized woman was the victim."

Indigestion in Infants.—Dr. L. Emmett Holt of New York addressed the Pediatric Society April 9th on "Some Forms of Indigestion in Infants and Young Children, with Especial Reference to Their Dietetic Treatment." Dr. Holt spoke mainly of the chronic forms of indigestion, saying that the direct inheritance of indigestion is questionable. He also said that the average obstetrician has but little knowledge of proper infant-feeding and the pediatrist should have charge of the infant from the beginning instead of when it is one month old if the best results are to be attained. Infants can be accustomed to cow's milk only by careful training. Dr. Holt prefers milk from the Walker-Gordon Laboratory to any other infant food, the usual initial formula being 1 per cent. fat, 6 per cent. sugar, and 5 per cent. proteids.

Test of Food Is Comfort of the Child.—The healthy child is absolutely comfortable and this should be the condition sought in artificial feeding. Gain in weight may not be immediate and constipation frequently is present. But if the child is entirely comfortable wait for gain in weight and do not pay too much attention to the constipation. It will generally disappear when the food is made stronger. Vomiting may be a troublesome symptom. Gastric dilatation rarely has much to do with that condition, it being due more frequently to high fat percentages than to any other cause. In such cases avoid milk and cream and use milk and lime-water. When vomiting is caused by mucus, stomach washing is the only remedy. Attacks of acute indigestion may be caused by a surprisingly small quantity of cow's milk. Dr. Holt cited cases to show that these attacks may not be due to infection from the milk, as is generally supposed, but to the fact that the milk causes a condition favorable to the growth of germs already present. Death in these cases is due to the condition of the child and not to the milk. In view of this, careful attention

should be paid to the history of the child and if previous attacks of indigestion have followed the use of cow's milk, its use should not be begun early.

Analysis of Breast Milk Is Unsatisfactory.—The analysis of breast milk to determine the cause in cases of indigestion in nursing infants is unsatisfactory. The true test is effect of the milk upon the child. If there is persistent indigestion with no gain in weight the case is hopeless and nursing should be stopped. If there is gain in weight, efforts should be made to overcome the indigestion. Change in diet is often of the utmost importance. Less milk, with higher percentages, and plain water between meals often give good results. Too much attention should not be paid to traditional opinions regarding the amount of fat and proteids in formulæ. The comfort of the child should be the real guide in any system of infant-feeding.

Pennsylvania Hospital.—The Pennsylvania Hospital, termed by its historian, Dr. Thomas G. Morton, "the Mother of American Hospitals," will celebrate on May 11th next the 150th anniversary of its establishment. It was founded by the Assembly of the Province of Pennsylvania in 1751, in response to a petition in the handwriting of Benjamin Franklin, which was drawn up at the suggestion of Dr. Thomas Bond. Funds were not plentiful, and it was only on the offer of Drs. Thomas Bond, Lloyd Zachary, and Phineas Bond to give their services for three years that a modest grant of £2,000 was made, to be supplemented by a like amount from private subscription. Since its inception, to quote from the Philadelphia *Ledger*, "the hospital has either led or kept pace with advancements in surgery and medicine. It was the first to introduce clinical teaching in this country, the first bedside instruction in medicine being given by Dr. Bond. It was the pioneer in this country in caring for the insane, and led the world in evolving and perfecting the humane and rational treatment of those suffering from disordered minds." Another circumstance that gives it fame is that it is the one great hospital in the country that has cared for wounded soldiers of the colonial and Revolutionary wars, the War of 1812, the Mexican War, the Civil War, and the Spanish-American war.

CHICAGO.

Sanatorium for Consumptives.—Members of the Illinois Society for the Prevention of Consumption are pushing the bill for a State sanatorium pending before the Legislature. As referred to the Committee on State Charities, the bill provides for the appropriation of $200,000 to purchase a site and construct appropriate fireproof buildings, and the building is to be known as the Illinois State Sanatorium. Provision is made for the appointment of three trustees by the Governor, under whose direction the appropriation shall be spent and the institution managed. Consulting physicians, a superintendent, a medical staff and other employes are to be selected by the Board of Trustees. Following is the section relative to the admission of patients: "The Superintendent and consulting physicians shall formulate such rules as they deem advisable, regulating the admission of persons afflicted with tuberculosis to the Illinois State Sanatorium, keeping in view the fact that in the early stage the disease is curable, and that the greatest good to the State is derived from the restoration to health and to their families of the dependent sick; therefore, the cases of incurable tuberculosis should be cared for in a separate institution, but perhaps on the same site, the said rules of admission to be approved by the Board of Trustees. The charges for the support of the inmates of the said institution as are of sufficient ability to pay for the same, or have persons or kindred, towns or cities, bound by law to maintain them, shall be paid by such inmates, such persons, or kindred towns or cities at a rate to be determined by the Trustees of said sanatorium. All persons citizens of the State of Illinois who shall be admitted to the sanatorium, and are indigent, shall be given medical care and board at the expense of the county of which they are residents." The passage of the bill is strongly urged as a step toward checking the increase of the prevalence of consumption. Authorities of the State Board of Health and officials of the Chicago Department of Health favor the bill.

Home for Epileptics.—There are five thousand epileptics in the State of Illinois, and the Board of Charities declares they should be removed from asylums and poor-houses and placed in an institution where they may receive proper attention. Two sites are suggested for the home—Grand de Tour, in Ogle County, and Elsah, in Jersey County. Three members of the Board favor the selection of Elsah, while only two recommend Grand de Tour. The necessity of providing a place for epileptics, so they may escape from their undesirable condition in almshouses and asylums, is acknowledged by all acquainted with the question. Most epileptics are able-bodied and require outdoor work and exercise. Ordinary treatment for the insane or feeble-minded is entirely inapplicable in epileptic cases. Chicagoans interested in the movement hope the Senate Committee will decide to locate the institution at Grand de Tour, not only because it is more advantageously located for this part of the State, but because, in the opinion of physicians and specialists, it is more healthful and better adapted for such a home.

The Skull and Its Contents.—Dr. W. H. Earles, of Milwaukee, read this paper. The conclusions of the paper were based upon the following propositions: (1) As a general proposition, it is safe to say that any injury to the head sufficiently violent to product fracture of the skull bones is also sufficiently violent to seriously injure the brain, its coverings or interfere with its circulation. (2) Many times blows upon the head without fracturing the bones produce such

injuries to the brain as to cause serious trouble, both present and prospective. (3) Where such injuries exist, their treatment implies immediate effort to repair the soft parts. With present knowledge of the anatomy, physiology and focal centers of the brain, combined with the deductions drawn from past experiences in the surgery of this organ, both as regards interference and non-interference with traumatic and pathological conditions associated therewith, but one position is tenable, and but one conclusion logical, namely, that much more is possible than has been accomplished. Couple this conclusion with the safety afforded by surgical cleanliness, and it becomes fairly presumptive that reasonably successful surgical work upon the brain is possible, and from this work reasonably accurate results may be predicated. In summing up the author said he would use the trephine or chisel in every case of severe injury to the head, as evidenced by the symptoms and degree of force received. He would carefully examine the soft parts and, if found injured, would repair them at once. If this is not done at the time of the injury, then it should be done as soon thereafter as circumstances will admit, in the hope of preventing secondary sclerosis. When sclerosis has become established, the diseased area should be thoroughly excised, substituting healthy and comparatively non-irritating union for old diseased conditions. The physician should be certain that the offending area is the one removed.

College of Medicine and Surgery.—This institution has increased its capital stock from $10,000 to $50,000.

Memory of Dr. Thompson.—The memory of the late Dr. Mary H. Thompson is to be perpetuated by a large marble bust by Daniel Chester French, the sculptor, to be placed in the Art Institute.

GENERAL.

Appointment of Dr. Pozzi.—Dr. Samuel Pozzi has been appointed Professor of Clinical Gynecology in the Medical Faculty of the University of Paris.

National Association for Study of Epilepsy.—Among those who will read papers at the next regular meeting of this Association are Dr. A. E. Osborn, Wharton Sinkler, H. C. Rutter, W. F. Drewry, Max Mailhouse, Prof. Paul Kovelevsky of St. Petersburg, W. Aldren Turner and G. Penn Gaskell of London, Frederick Peterson, B. M. Worsham, L. Pierce Clark and Wm. P. Spratling.

German Physicians' Association.—Berlin has an association of physicians who pay a sum equal to 5 per cent. of their income tax every year into the treasury. This yields about $12,000 a year, which is given to those members and their families who need help.

Plague at Ann Arbor.—It is decided that the case of suspected plague reported in last week's Medical News is one of true bubonic plague. The student, C. B. Hart, contracted the disease as a result of laboratory work with the organism.

A Doctor's Gift to the Blind.—We learn from the *Lancet* that Mr. George Scale, a medical practitioner of Portsmouth, England, who retired from practice in 1872 by reason of blindness, has left to the Corporation of Portsmouth a sum of $100,000 to provide annuities for the blind. The applicant must be over thirty years of age and be found worthy. The amount of each annuity is fixed at $150.

Association of American Medical Colleges.—The next regular meeting of this association will be held at the Hotel Ryan, St. Paul, Minnesota, Monday, June 3, 1901. It will consist of two sessions, an educational session and a business session. The educational session will be opened at 2 p. m. by the President's Address, followed by several papers of medical pedagogic interest. To this session all persons interested in medical education are respectfully invited. The representatives and associates of the Association of Southern Medical College have received a special invitation. The members of the Confederation of State Examining and Licensing Boards are also invited. There will also be an exhibition of work done in medical colleges. At 8 p. m. the business session will be held at which the amendments to the Constitution proposed by several colleges will be considered. The report of the judicial council, the election of members and the election of officers for the succeeding year will close the program.

Preliminary Program of the Ohio State Pediatric Society.—The annual meeting of this Society will be held in Cincinnati, May 7th, beginning at 2 p. m. and continuing through the evening and next forenoon until the program is completed. The Society will meet in the Convention Hall, Grand Hotel, which hotel will be the headquarters of the Society. The following papers will be read: "Phlyctenular Conjunctivitis," by S. C. Ayres, M.D., Cincinnati, O.; "Pemphigus Neonatorum," by A. Ravogli, M.D., Cincinnati, O.; "Infantile Nourishment," by George M. Clouse, M.D., Columbus, O.; "The Necessity of a More Perfect Aeration," by H. H. Spiers, M.D., Ravenna, O.; "Bloodless Reduction of Congenital Hip Dislocation," by Walter G. Stern, M.D., Cleveland, O.; "Chorea," by James H. Taylor, M.D., Indianapolis, Ind.; "Criminals and Defectives, How to Reduce Their Numbers," by J. R. McCally, Dayton, O.; "Dosimetric Medication in Pediatric Practice," by M. Borts, M.D., Cleveland, O.; "Ohio Institution for Feeble Minded," by G. A. Doren, M.D., Columbus, O.; "Coal Tar Derivatives in Children's Diseases," by J. B. McGee, M.D., Cleveland, O.; "Acute Intestinal Obstruction," by F. F. Lawrence, M.D., Columbus, O.; "Chronic Intestinal Obstruction, with Report of a Case," by D. S. Hanson, M.D., Cleveland, O.; "Purulent Ophthalmia in the New-born," by Edward Lauder, M.D., Cleveland, O.; "Malignant Diseases in Children, with Report of a Case,"

by J. V. Kofron, M.D., Cleveland, O.; "Strumous Keratitis and Conjunctivitis," by Derrick T. Vail, M.D., Cincinnati, O.; "State Provision for the Care and Treatment of Crippled Children," by Frank H. Darby, M.D., Columbus, O.

Fifth International Congress of Physiologists.—In conformity with the resolution passed at the Fourth Congress at Cambridge, England, on August 26, 1898, the Fifth International Congress of Physiologists will be held this year at Turin, from the 17th to the 23d of September, in the Physiological Institute of the University, directed by Professor Angelo Mosso. The sessions of the 17th, 18th, 19th, and 20th of September will be occupied with the ordinary business of the Congress (demonstrations and communications). The 21st and 23d of September will be devoted to supplementary general sessions, at which the reports of the International Commission appointed at the Cambridge Congress (dealing with the standardizing of recording apparatus, calorimetric methods, and of units in the physiology of the senses, etc.) will be submitted, as well as other business.

In addition to the General Secretaries for the work of preparation for the Fifth Congress, Professor Frederic S. Lee (Columbia University, New York), Secretary of the American Physiological Society, will discharge secretarial duties in America. American physiologists who intend to be present at the Fifth Congress are requested to notify him.

English Drunkard Legislation.—An Habitual Drunkard's Bill introduced in Parliament recently by the Bishop of Winchester proposes novel methods of protecting the wife and children of the habitual drunkard by punishing saloon-keepers who sell drink to the habitual drunkard. The bill proposes the establishment of a black-list of persons declared to to be habitual drunkards, whose names are to be notified to the keepers of licensed houses within a specified area, with a direction not to serve them, and also makes the offence of being drunk when in charge of a child punishable by a special penalty. The status of an habitual drunkard is acquired by a man being within twelve months three times convicted of certain offences found by the court to be due to or helped along by drink. In such cases a man is to be declared an habitual drunkard. The order so declaring him is then to be sent to all license-holders within a certain area, and also to the chief police officer for the district. Serving such a drunkard with intoxicating drink renders the license holder liable to a fine of $50 for the first offence and to a fine of $100 for subsequent offences, the drunkard also being liable to a fine of not more than $5. An alternative penalty is that instead of fining the saloon-keeper $100, his license be suspended for three months. The license of any saloon-keeper so convicted is to be endorsed accordingly. From the favorable consideration which this proposed bill has received, it is considered reasonably certain that some of its features will become law.

Obituary.—Dr. Frank Wayland Abbott, regarded as one of the foremost oculists in Western New York, died at his home, No. 523 Franklin street, Buffalo, N. Y., April 9th, after a protracted illness. Dr. Abbott was graduated from the University of Buffalo in 1866, and was oculist in chief at the General Hospital and the Eye, Ear, and Throat Hospital of Erie County.

Dr. William F. McClelland, who was one of the first physicians to make a study of the climatic influences of the mountain region upon pulmonary diseases, and who was widely known in America and Europe, through the performance of many difficult surgical operations, died April 12th at his home in Denver, Col., aged eighty years. Dr. McClelland left a large estate.

Dr. Block, of San Francisco, who has been studying in the Berlin clinics, died at Berlin, April 12th, of scarlet fever.

CORRESPONDENCE.

AN OBSTINATE CASE OF HICCOUGH.

To the Editor of the Medical News:

Dear Sir: I wish to report briefly an obstinate case of hiccough. Carl J., aged twelve years, previous health good. Three years prior to this attack he had a similar one which lasted fourteen days. I did not see him during that attack, but have the history from his parents and family physician. During that attack he hiccoughed continuously. A mixture of bromide of potash and tincture of valerian relieved him. He has fair complexion, light hair, and is very intelligent. There is no history of any nerve trouble in parents or grandparents.

I saw the case throughout the second attack, and was met twice in consultation by two other physicians. I used asafœtida, acetanilid, bromides, chloral, camphor, ipecac, in emetic doses, soda, valerian, ether, chloroform, morphine, opium, electricity, mustard to stomach, and along the course of the pneumogastric nerves. A mixture of morphine and chloroform in simple syrup relieved him for eight or ten hours. This was the only thing that did him any good at any time. The appetite was good, but occasionally he vomited the food.

He was bright and cheerful most of the time. There was no rise of temperature. He slept comparatively well, although the hiccoughing continued with the same regularity as when awake. He seemed to have formed a habit of hiccoughing. This continued for sixty-five days, with the exception of one period of eight or ten hours, when it finally "wore itself out," and he got well in spite of treatment, and so far as I know has had no other attack.

C. C. Hubbard, M.D.

Worthville, N. C.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 8, 1901.

THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—ITS MEDICAL STAFF AND ITS BOARD OF MANAGEMENT—AN ANOMALOUS OFFICIAL—CEPHALITIS NOSOCOMIALIS—A VICTORY FOR THE DOCTORS—MEDICAL M.P.S—THE INTERNATIONAL CONGRESS ON TUBERCULOSIS.

The thing most talked about in medical circles here at the present moment is the great quarrel between the governing body and the medical staff of the National Hospital for the Paralyzed and Epileptic. The institution is well known throughout the medical world by the work in neurology that has been done there during the last thirty or forty years by such men as Hughlings Jackson, Buzzard, Bastian, Ferrier, Gowers, and Victor Horsley. On this account a brief narrative of the facts which have led to the biggest scandal in hospital affairs that we have had for many years may be interesting to American readers. The National Hospital is managed by a board of laymen, the chairman of which is Mr. G. W. E. Russell, a member of the great Whig family whose head is the Duke of Bedford. He was for some years a Member of Parliament and more than once held subordinate offices under Gladstone. He is the author of a monograph on that moral, but mobile politician which would be described by the French as "*Gladstone intime*," and he has added to the gaiety of club smoke-rooms by a miscellaneous assortment of chestnuts of various degrees of antiquity entitled "Collections and Recollections."

What is more to the present purpose, Mr. Russell is an ardent member of the antivivisection church militant. This of itself would be enough to put him out of harmony with a medical staff which includes men like Ferrier and Horsley who, in the eyes of antivivisection fanatics, are what the Scarlet Woman sitting on the Seven Hills is in those of antipopish bigots. But in addition to this particular "lost chord" of sympathy, there is yet another in the person of Mr. Burford Rawlings, a paid official who rejoices in the title of "Secretary Director." The office is as unique as the title, for the Secretary Director is practically the supreme authority in the hospital. It is only fair to state that Mr. Burford Rawlings has done much for the material prosperity of the hospital. He is a capable man, with a considerable talent for that peculiar kind of literary composition which is intended to screw the heartstrings of the charitable to subscription pitch. But his success in his proper sphere has had the not uncommon result of producing a form of enlargement of the skull which from the special frequency of its occurrence in persons concerned with hospital administration might perhaps be termed *cephalitis nosocomialis*. This condition, though as yet unrecognized by pathologists, should find a place among "occupation diseases" as "the swelled head of hospital secretaries." As the National Hospital has grown in importance and reputation, the mind of its Secretary Director, as Byron said of the visitor to St. Peter's in Rome, expanding with the genius of the spot, has grown colossal; and from the *servus servorum Dei* who do the work of the hospital, he has aspired to become their master. The medical staff on their part have collectively and individually a just sense of their own merits; some of them, indeed, have all the qualities of genius—except the unconsciousness which is one of its "notes." They naturally resented the threatened establishment of a dictatorship, and they said in effect, as our House of Commons did in the century before last, "that the power of the Crown had increased, was increasing and must be diminished." This, however, was not at all the view of the hospital "Crown," and the Secretary Director found his board as subservient to his dreams of empire as the Roman Senate was to those of Cæsar Augustus. But he could not bring the rebellious staff to what, in the style of addresses to the sovereign, is called a "loyal and dutiful" attitude. They continued to urge their demand for representation on the Board of Management, and they even had the audacity to issue a statement to the Governors in which it was alleged that, so far from all being for the best in the best of all possible hospitals, there were serious defects in the provision for the care of the patients and in the administration generally. This manifesto transformed what had previously been a policy of "pin-pricks" carried on within the walls of the hospital into open war before the world, or such fraction of it as reads the London newspapers. The board, which in density at least is a fine sample of British "heart of oak," has stolidly resisted the demands of the staff, apparently out of sheer incapacity to see the situation in its true light. At a meeting held on March 23d, however, it was at last made plain to them that the governors and subscribers are determined that the doctors should have a fair hearing. Mr. Russell delivered a speech in defence of himself and his colleagues in which he almost rivaled one of the most marvelous oratorical feats of his great exemplar. In the life of Mr. Childers, one of Beaconsfield's "extinct volcanoes," which has just appeared, it is related that Gladstone on one occasion, when he was afraid of Russia but did not wish to say so, got the House of Commons to vote him eleven millions of pounds without once mentioning Russia. With similar dexterity of evasion Mr. Russell gave an account of the war between his board and the staff, without once mentioning the Secretary Director. Notwithstanding all the shuffling and sophistry of the supporters of Mr. Burford Rawlings it was decided that an inquiry into all the matters in dispute should be made by an impartial committee. It is "significant of much" as Carlyle used to say, that this Committee was not appointed directly by the meeting, which preferred to depute the task of selecting it to an intermediary committee.

There the matter rests for the time, but there can be little doubt that the doctors will win, and that the Secretary Director will find himself in the unpleasant dilemma presented to a former President of the French Republic and will be called upon *se soumettre ou se démettre*. The antivivisection interest will be worked for all it is worth against them. But they have the support of the whole medical profession at their back, and what Sheridan says of the stage may be said of doctors, "When they do agree their unanimity is wonderful." The public is beginning to see that the resignation of the staff would mean the ruin of a hospital which has come to be a Mecca of neurology, attracting scientific pilgrims from the ends of the earth. It is said that the resourceful Secretary Director has a new staff ready to take the place of the present one in case he succeeds in driving them from the field. But in the whole country there could be found no men worthy to unloose the latchets of the present staff's shoes, and none could be pressed into so degrading a service but men, in a professional sense, akin to the ragged recruits with whom Falstaff refused to march through Coventry.

Medical practitioners in England as a class have little time and less inclination to take an active part in political life. Politicians treat the profession as a negligible quantity, and it is very hard to move the legislature to do anything at all for the protection of its interests or indeed for the furtherance of schemes for the public welfare which owe their origin even indirectly to medical influence. In the House of Lords for the first time in the history of the nation there is, in the person of Lord Lister, a peer representative of medicine. In the House of Commons the profession is represented by less than a dozen members in an assembly of 670. It could scarcely be expected that this handful of special knowledge could leaven such a mass of ignorance, prejudice and indifference in matters medical. Yet our medical M. P.'s are on the whole fairly vigilant in seeing that the professional commonwealth suffers no detriment. Some of them are, to parody a phrase of Johnson's, politicians generated by the corruption of professors of physic, but others are worthy representatives of medicine and are held in general respect by the House. Sir Michael Foster, the Cambridge Professor of Physiology, who sits for the University of London, of which he is a graduate, lately made his maiden speech in a debate on pure beer—a question to which the recent revelations as to the connection between arsenic poisoning and beer has given "actuality." The ordinary M. P.'s *a priori* idea of a scientific professor is that he must be an unattractive blend of gravity and dulness. Sir Michael Foster's speech, therefore, was an agreeable surprise, for it was amusing as well as enlightening. If he can rid himself of a certain donnishness of manner, which is a predominant characteristic of men belonging to what are called here the older Universities (Oxford and Cambridge, to-wit), he is pretty sure to acquire considerable influence in Parliament. This he may be trusted to use for the promotion of medical science. Sir Walter Foster is another medical M. P. who is often confounded with Sir Michael, though no two men could be more utterly different in temper of mind or in personal appearance. Sir Walter Foster was a henchman of Gladstone, who gave him the title which enabled him to disencumber himself of his aggressively Oriental forename, Balthazar. He was a hospital physician at Birmingham, and has written on ailments of the heart and other parts. His marriage with the daughter of a wealthy philanthropist has made him independent of his profession, though he still sits at the receipt of custom when there is a chance of any coming his way. But his true vocation is politics. He is a passed master in all the arts of the wire puller and for a time disputed the supremacy of Chamberlain at Birmingham. He might be a power—of the second or third magnitude—in the House of Commons, but for the fact that he too obviously, like the Smith in the *Fair Maid of Perth*, fights for his own hand.

Dr. Robert Farquharson is one of the most popular members of the House of Commons. He was for some time a surgeon in the Guards; and afterward medical officer at Rugby, the school of which Thomas Arnold (the father of Matthew Arnold) was headmaster. Dr. Farquharson's next avatar was as a lecturer at St. Mary's Hospital, London, and, like most teachers, he felt that his position called upon him to publish a book. His "Manual of Therapeutics" was for a long time in high favor with the ingenuous youth of English medical schools. Owing to the death of a cousin Dr. Farquharson virtually retired from the profession some twenty years ago, blossoming into a Scotch "laird" and a Member of Parliament. Though in his capacity of legislator he does not care to be too much identified with medicine, he maintains an active interest in his profession. He was believed to be the one man in Parliament who understood the Public Health (for Scotland) Act, a movement as long and quite as abstruse as the "Shorter Catechism." Dr. Farquharson is too unambitious, and it may be added too straightforward, a man to make a great figure as a politician, but he may find compensation in the knowledge that he is universally popular and trusted both by Parliament and by the profession.

Sir John Batty Tuke, who succeeded the late Sir William Priestley as M. P. for the Universities of Edinburgh and St. Andrew's, has not been long enough in the House of Commons to have made his mark there. He has considerable reputation as a specialist in mental diseases and has held the dignified office of President of the Royal College of Physicians of Edinburgh. Of the other medical M. P.'s there is little to be said. Mr. Dillon (once described by his own colleagues of the Irish party as a "melancholy humbug"), Sir Robert Finlay, the Attorney General, and Sir George Pilkington, who owes his political im-

portance to a successful venture in the matrimonial market, were all doctors by first intention, but can now scarcely be regarded as being within the pale. Dr. Robert Ambrose and Dr. Mark Antony Macdonnell, both of whom though practising in London are members for Irish constituencies, are little heard of in Parliament and not at all outside it. Dr. Tanner, another Irish member who won notoriety by his ultra-Hibernian rowdiness, is so broken in health that he is unlikely ever again to vex the soul of the Speaker. Dr. Rutherford Harris, the *fidus Achates* of Cecil Rhodes, was returned at the last election, but has just been unseated for bribery (proved against his agent). He too quickly found medicine too narrow for his expansive ambition, and found wealth in diamonds which he would hardly have found in drugs.

Since the dispatch of my last letter the prospects of the forthcoming International Congress on Tuberculosis have become distinctly brighter. The King has after all consented to be Patron, and the smile of royalty has materially stimulated the inflow of funds. The Congress will probably be opened by the Duke of Connaught as representative of the King.

MODIFICATION OF SCHLEICH'S ANESTHETIC MIXTURE—CAUSE OF RHEUMATISM—ISOLATION OF SPECIFIC CAUSE—SOME PATHOLOGICAL CONSIDERATIONS—VALUE OF URINARY EXAMINATION—RHEUMATOID ARTHRITIS: ITS RELATION TO RHEUMATISM.

J. R. Probyn-Williams, at the Society of Anesthetists, March 1, 1901, in conjunction with H. Barnard and R. J. Howard read a paper on a modification of Schleich's anesthetic mixture, as recently suggested by Wertheim of Vienna. It consists of chloroform, one part, petroleum ether, one part and sulphuric ether, two parts. Petroleum ether is now recognized in the appendix of the British Pharmacopœia where it is stated to have a specific gravity of 0.670 to 0.700. That used in their experiments showed only 0.643. With petroleum ether alone it was very difficult to kill the animals (cats) experimented with. The heart's action became more rapid, blood pressure in the arteries slowly fell, in the veins slowly rose. This increased venous pressure apparently explained the increase in the heart's volume. All these features contrast strongly with those shown by chloroform alone. With the above mixture hardly any circulatory signs were noted until the anesthetic was pushed to the extreme. In practice they have used it thirty-four times with great success on operations varying from five to forty-five minutes. The induction of anesthesia is prompt, usually less than eight minutes, easy, free of cyanosis or other cardio-pulmonary disagreeable symptoms. The hypersecretion of mucus so often present with ether was commonly absent. The degree of anesthesia was deep enough for all operative purposes with complete muscular relaxation, but so light that the patients recovered very promptly. The pupils reacted just as in the A. C. E. mixture. Shallow breathing was not observed so long as the mixture was given sufficiently freely. There were no serious after-effects. Vomiting resembled that of chloroform narcosis. The effects of postural change had not yet been determined.

F. J. Boynton and A. Paine, at the Chelsea Clinical Society, March 12, 1901, read a paper jointly prepared on the infective character of acute rheumatism, and more especially with the relation which the various chronic forms bear to the causation of the acute type. In their experience rheumatism is a very definite disease, running a definite course and with rather definite lesions and symptoms. All this strongly points to the suggestion that a distinct germ is at the bottom of the disease. If, now, a germ is constantly recoverable from patients suffering with rheumatism and when injected into animals constantly produces the same lesions, it is highly probable that these germs are the cause of the disease. Pleurisy, pericarditis and nodules are just as much direct manifestations of the disease as are the polyarthritic signs. To hold that the joint lesions are the only true ones is not in accordance with the modern ideas of the disease. Although the salicylates are of value in some cases, because they are of service in a given one is not a proof that an obscure lesion is essentially rheumatic. They think they have weakened the position of those who claim that virulent rheumatism is the result of a mixed infection, because they have demonstrated that at the site of the lesions the rheumatic germs are readily destroyed and are therefore very difficult to find. From fourteen patients with rheumatic fever they have isolated a diplococcus which grows in chains in fluid media and in staphylococcic masses in solid media. Triboulet before and Wasseoneau and Malkoff during the time they were working had also isolated a diplococcus from acute rheumatism. During the past year F. Meyer has been experimenting with cases of rheumatic angina and has recovered a diplococcus which in most of its morphological characters and in all of its general results in animals after injection resembles the germ they have been describing. Their experiments have been more detailed than those of other observers and though various observers have used different media the general character of the germs are so similar as to make it very probable the cocci are identical. Meyer used a strongly alkaline and they a feebly acid medium, but the germ of each grew best on blood agar which is faintly alkaline. They have isolated this germ three times from patients with rheumatic pericarditis from the blood, twice from the throat, four times from the pericardium itself, growing them also in the exudations, twice from the urine, once from the cardiac valves and once from a rheumatic nodule. The lesions produced

in a rabbit after inoculation are identical to those produced in man. For the inoculations undoubted cases of rheumatic fever were chosen and not a shadow of doubt was entertained by the physicians Cheadle, Lees, Penrose and Garrod in attendance as to the nature of the disease. They therefore believe that if they strip the disease of valvulitis, polyarthritis, pericarditis, pleurisy and nodules it is very difficult to believe in its existence except perhaps as a constitutional tendency. They thought therefore that the pathology of the disease is now on a much firmer basis than heretofore and that when the toxins are once isolated the lesions will probably still further be explicable, both in acute and in chronic cases. They have repeatedly found the diplococcus in the joints of injected rabbits and equally frequently found them in those of rheumatic patients. In general such facts bring rheumatic joints into line with those found in pneumonia and gonorrhea as manifestations of a local infection. According to the researches of Bannatyne, Wohlmann and Blaxall, rheumatoid arthritis must also be included in this series. Gouty and syphilitic joints remain yet as those unexplained by any discovered micro-organism. It seems likely that gout is not of this class, but that syphilis very probably is, but the germ remains still to be isolated. The kidneys must be regarded as the chief avenue of elimination of the micro-organisms. The parenchymatous changes were not necessarily permanent. Although a moderate albuminuria and in malignant cases hematuria and a large quantity of albumin appeared, it seems as though the kidneys should recover without any very great damage. In rheumatism it is more and more desirable to study the urine and ascertain how the organs are acting. Probably it will be found on such observations that albuminuria of the cyclical or evanescent type depends rather completely on rheumatism or its manifestations. The similarity between gout and rheumatism suggests the indication for regular urinalysis in all cases of the latter disease. Some of the cases of malignant endocarditis they have become satisfied are the result of pure rheumatic infection without supposing the intervention of any mixed infection. Again, in certain of the joint lesions involving a destruction of the cartilages themselves, it is quite certain that only the diplococcus was at work. Hence we must assume that the disease is capable of very toxic effects, systemically and locally in the heart-valves and joint-tissues, depending as in all infections upon the virulence and quantity of the infecting germs and upon the general focal resistance of the patient.

N. C. Macnamara, in the discussion, said that the various toxic chemical products of germs within the system were of highly different degrees of destructive effects. For example, there are the rapidly dangerous action of the pyemic processes, the exceedingly slow course of leprosy and the arthritic manifestations of gonorrheal arthritis which may be taken as an example of processes midway between the other two. No possible doubt exists as to the truly infective nature of the gonorrheal joint affections, nor to the abundant presence of this coccus in the joint tissues. Again, the final results in the joint are peculiarly and specially analogous to those of rheumatoid arthritis. Todd years ago dwelt on the possible relation between the leucorrheal discharges and this absorption into the body from the uterine cavity and the old joint affections of the rheumatoid arthritic type in women. In 1885 Macnamara had seen a twenty-five-year-old woman in whom the presence of very extensive dental caries was the cause of a rheumatoid arthritis going on to considerable deformity and ankylosis. Since then in all cases of arthritis rheumatodea he has regularly sought and treated any possible source of general septic absorption, as the first step in a rational treatment. While it is perfectly true a percentage of the cases depend entirely upon rheumatism or gout or a neurosis, another large proportion are attributable to some form of constant chronic septic absorption, which must be removed or in some way alleviated in the true treatment.

C. O. Hawthorne discussed the relation existing between acute rheumatism and chronic rheumatoid arthritis as cause and effect, admitting that acute rheumatism is manifested by fever, pain and swelling in various joints, that subacute rheumatism is identical with what is also called rheumatic fever. Rheumatoid arthritis is a chronic condition which some authorities regard as the chronic stage of the others or as the clinical manifestations of a different disease. Among the causes of chronic rheumatoid arthitis distinct from any relation to subacute or acute rheumatism are the action of germs in the joints, of septic absorption from a focus elsewhere in the body and of a nervous disease variously assumed to be either primarily located in the spinal cord or in the pelvic or other viscera and from these the cord becomes secondarily involved and then the joints. There are some cases of this affection which follow directly upon an attack of acute or subacute rheumatic fever, others which occur in families in which many of the direct connections of the patients have had rheumatism. The absence of a cardiac complication in rheumatoid arthritis can no longer be accepted as the dividing line between the two diseases, because in rheumatism the heart is oftenest affected in childhood, next in adolescence, and so on progressively less and less as age advances. Most cases of rheumatoid arthritis occur in midlife and later. Charcot says that cardiac disease is of rather frequent occurrence in the true forms of this disease. Again, there are cases where a differential diagnosis between true rheumatism and true rheumatoid arthritis is wellnigh impossible. Trousseau has lately demonstrated cardiac trouble in "nodular rheumatic" disease. The speaker had himself lately seen it appear in a case of well-defined rheumatoid arthritis. The nodules of the skin, so common in childhood and youth during

rheumatism, may also appear during the rheumatoid arthritic conditions, but are more persistent, like the disease itself. Since such nodules appear in gout and in other conditions, too much can not be assumed here, but certainly the fact is strongly suggestive. It is known that certain spinal cord diseases produce vast muscular diseases and atrophy and also are capable of affecting in destructive trophic changes the joints themselves. While this is true it is also a fact that in any joint affection whatever involving rest the muscles which are concerned in its functions atrophy. This is a highly more likely cause of the muscular atrophy than a spinal lesion on account of the very great rapidity of the change. On the other hand, it is certainly conceivable that the joint lesions no matter what their cause may be set up by centripetal impulses, which, reaching the cord, initiate trophic centrifugal impulses which atrophy the muscles. Whether or not the rheumatoid arthritic changes are manifestations of true rheumatism he could not say. Like many other things in medicine too little is at the moment known about all this class of disease for us to venture any definite opinion or do more than indicate possibilities.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held March 5, 1901.

The President, Joseph Collins, M.D., in the Chair.

Patient for Diagnosis.—Dr. Joseph Collins presented for diagnosis and discussion a boy of ten years who presented a complex of symptoms which could not easily be placed under any one designation. He was one of twelve children, seven of whom in infancy had had marasmus or gastro-intestinal disorders. The present ailment had begun about nine months ago, at which time the boy had commenced to "hop." He complained of pain in the great toe of the left side, and also of pain in the precordial region. He had then been taken to the Mt. Sinai Hospital and while there it had been noted that there was some stiffness or weakness in the lower limbs on walking. This impairment of motion had steadily increased, so that at the present time he was practically unable to walk more than a few steps. According to the history, there had been early in the disease great difficulty in commencing the act of micturition. At present there were no symptoms referable to the bowel or bladder. He has a peculiar waddling gait, and when standing, there is a typical flatfoot. There is a peculiar knocking together of the thighs. The spasticity of the gait had been found, on closer examination, to be more apparent than real. There is a marked ankle clonus. There are no sensory disturbances. He gets up from the lying position as children do in the early stages of progressive muscular dystrophy. These symptoms, the speaker said, seemed to point distinctly to a lesion in the spinal cord in the crossed pyramidal tracts.

Dr. B. Sachs said that he had been much interested in this boy at the time he had been in the hospital. The combination of the waddling gait, so characteristic of the dystrophy, with an increase in the reflexes, seemed to be especially unusual. When the boy was stripped, it seemed to him very evident that he had progressive muscular atrophy of the Landouzy type. In addition to this he thought there was a subacute myelitis, possibly of traumatic origin. There could be no question that the calves are hypertrophied. This diagnosis had been arrived at only after careful observation for a period of several weeks. The frequent falls which such children have would easily explain the occurrence of a subacute myelitis. The spasticity had been more marked nine weeks ago.

Dr. Joseph Fraenkel said that the most prominent symptoms were those of disease of the lateral and posterior columns. At first sight the gait was that of ataxic paraplegia. On the supposition that the myelitis was the later disease one would expect less evidence of the second. The evidences of pseudohypertrophy were very marked. He inclined to the diagnosis of a subacute multiple sclerosis of a paraplegic type.

Dr. Collins thought it was safe to assume that the boy had a dystrophy, but not that there was a subacute myelitis. No one could say whether the changes in the spinal cord which accompany the dystrophies are not of such nature that double ankle clonus and double knee jerk might not develop. It was certainly a form of dystrophy which does not conform strictly to the description of any usually given. If there were an implication of the cord it was confined entirely to the crossed pyramidal tracts. He would not be willing to admit there there are any changes in the spinal cord except secondary ones.

Progressive Muscular Dystrophies with a Report of a Postmortem Examination.—Drs. B. Sachs and Harlow Brooks presented this paper. The authors stated that it could not be denied that there was any sufficient distinction between the amyotrophies and the dystrophies. In former years much stress had been laid on the muscular structure. Hypertrophied fibers were found in abundance in dystrophies, whereas in the amytrophies these fibers were not found. But later it had been shown that the hypertrophied fibers were found in other diseases than dystrophies. It was also a question whether the gray matter of the cord was affected in the primary dystrophies. The case to be reported was one of progressive muscular dystrophy of fifteen years' duration, yet the structural changes, as demonstrated by the

latest methods of staining, were very slight. The patient had been admitted to the Montefiore Home eleven years ago at the age of twelve years. Early in life the parents had noticed peculiar movements of the head and eyes. He had been in good health up to about the age of twelve years, when he had fallen and broken his leg. At the age of twelve years, after an attack of typhoid fever, it had been noted that the calves were decidedly hypertrophied. The head was enlarged and exhibited certain movements. There was a marked atrophy of all the muscles of the shoulder girdle, arm and forearm. The deep spinal muscles were intensely atrophied. The thigh muscles were atrophied. The case became an extreme illustration of a progressive muscular disease of the pseudohypertrophic type. The lad's intelligence was fair.

Muscular Pathology.—Dr. Brooks said that at the autopsy the organs were normal with the exception of an acute pneumonia and a slight myocarditis. There were no gross lesions of the brain or spinal cord. No lesion of the smooth voluntary muscular tissue could be found anywhere in the body. The psoas muscle showed extensive fibrosis. The muscles of the back all showed extensive fibroid replacement, and in places, there was a replacement by yellow fat. The trapezii were very extensively invaded. The most extreme changes were in the muscles of the calves where normal muscular tissue was lost. The autopsy had been done twenty-four hours after death, and at that time there had been no evidence of postmortem decomposition. On microscopical examination, the muscles showed extensive replacement with areolar tissue of the adult type. In the calf, occasional remnants of voluntary muscle were found. Most of the fibers of the psoas muscles were either larger or smaller than normal. The coarse striæ could usually be made out. The changes in the other voluntary muscles were of the same character, though varying in extent. In the occipital muscles the amount of connective tissue hyperplasia was less, but nuclear proliferation was prominent. Examination of various portions of the smooth muscles failed to show degeneration or hyperplasia of the connective tissue forming its framework. The heart muscle showed much less connective tissue increase than had been expected from the gross examination. The cardiac muscle was in a very natural condition, there being no atrophy, no abnormal pigmentation or abnormal nuclear activity. The blood vessels in the various tissues showed uniformly an increase in the connective tissue. No evidences of new vessel formation were found.

Nerve Cell Changes.—Numerous peripheral nerves were examined, but no appreciable degeneration of fibers was discovered. Only a few of the spinal ganglia had been properly prepared for examination, but these few showed a shrinkage of the ganglion cells similar to that produced by fixing agents. The irregular perilymphatic spaces were, however, found filled in with proliferating capsular cells, apparently indicating that this was not an artefact, but a distinct pathological process. Apparently the connective tissue of the ganglia had been increased. The connective tissue throughout the entire cord was found to be increased. The blood vessels of the cord were universally congested, but this was apparently of a hypostatic nature, due to the position of the patient before death. Nothing in the nature of a systemic degeneration of the fibers was found at any level. In the cervical region the ganglion cells in the anterior horn showed a slight nuclear eccentricity. The dendrites universally retained their power to respond to the stain. Occasionally the achromatic elements stained to a slight degree. Eccentricity of the nucleus was found more commonly in the dorsal cord than elsewhere. Lesions in the cells of the posterior horns were more infrequent than in the anterior horns. The most common lesion was a finely granular sub-division of the plaques, usually not involving the entire cytoplasm. A few of the lumbar cells showed an unusual amount of brown pigment collected about the nucleus.

Summary of Lesions.—The chief lesions were: (1) Extensive atrophy, which affected apparently all of the voluntary skeletal muscles and was confined to these muscles; (2) the production of areolar connective tissue and adipose; (3) slight general perivascular hyperplasia; (4) moderate interstitial myocarditis; (5) extensive degenerative changes in a few of the posterior root ganglia, and (6) rare changes in the cytoplasm of the ganglion cells of the spinal cord. The complete absence of the changes in the smooth muscles showed that the disease process was strictly localized in the voluntary muscular system. The authors did not look upon the connective tissue increase as an essential feature of the pathological process, but as an example of a universal function of this tissue to take the place of any tissue which had been removed. The perivascular connective tissue hyperplasia was very slight, and could not be considered as typical of the disease or as produced by it. Possibly the moderate myocarditis was associated with the connective tissue hyperplasia of the blood vessels. It did not seem to be in any way connected with the factors producing atrophy of the voluntary muscles. The changes in the posterior root ganglia seemed to be of great significance, though it was not clear that they bore any direct relation to the changes in the voluntary muscles. These degenerations seemed to be secondary in their nature, and dependent upon death or disease of certain portions of the neuron. A process similar to this occurs after amputation. There were no evidences of tract disease. The cytoplasm

changes of the ganglion cells of the cord were rare, and might represent the early stage of postmortem change.

Dr. Sachs said that these findings did not indicate that the cause was to be found in the gray matter of the cord. The disease represents a primary affection of the muscular fiber. The occurrence of stigmata of degeneration in so many cases of this dystrophy would lead one to think that these should be broadly classified under family affections. The question arose as to whether these muscular dystrophies were essentially progressive, and the statement was made that in every case the possibility of great improvement by systematic exercise should always be kept in mind in the early stage. Two illustrative cases, which had been followed for many years, were briefly reported.

Non-Progressive Cases.—Dr. C. L. Dana said that so far as the dystrophies were concerned, which were not strictly of the so-called pseudohypertrophic type but rather of the arm and leg type, it seemed to be a well-known fact that many of them cease to progress and live for many years in comparative comfort. He had personal knowledge of two families in which there were six or seven persons, going through three generations, who were afflicted with the leg or arm type of dystrophy. Some had lived to old age with only an inability to use the upper arm or perhaps the thigh muscles. One of these cases had been seen at many clinics in this city when thirty-nine years of age. The atrophies had begun at the age of nineteen, and had reached their height at about the age of twenty-nine. His weight had been reduced to eighty-eight pounds. A fairly hopeful prognosis could be given this class of cases especially when the atrophies do not begin very early in life. In his experience with pseudomuscular hypertrophy there had been only one case in which the disease had been really checked. This person was a woman of twenty-three in whom the trouble had begun at the age of eighteen. She had presented all of the typical symptoms of pseudohypertrophy of late development. He had put her on systematic exercises, and as a result the disease had not only ceased to progress, but she had absolutely improved. In another case which had been faithfully treated by exercise and massage for four years, there had been continued progress. Dr. Dana said he would like to have Dr. Brooks explain why there should be so much fibrosis in these cases. It might be that in the death of the muscle fiber an irritant poison is formed, and that this gives rise to the increased proliferation. There was a striking difference clinically between a typical spinal atrophy and an ordinary dystrophy, and he believed these diseases were very different in their origin also. The hereditary cases were of a type which is quite distinct from that of the acquired forms.

Early Invasion Not as Hopeful.—Dr. A. Wiener said that about six years ago he had presented to this Society a patient who was very much crippled in his muscular movements. In that case he had been so convinced that many muscular fibers were still intact that he had carefully trained him in exercises for six months. He had been again presented to the Society at the end of that time, and the improvement had certainly been very marked—indeed, the day previous he had been able to ride forty miles on his bicycle. On the other hand, in the dystrophies occurring early in life he did not believe much could be gained by exercise.

Dr. Leszynsky exhibited photographs of two patients whom he had had under his care for a number of years with pseudohypertrophy of the lower extremities and progressive muscular atrophy of the upper extremities. Both had died of some intercurrent disease at the age of twenty-five. Before he had seen them both had received massage and careful training in physical exercise.

Dr. Hammond said that he had recently made a postmortem examination on a case of pseudohypertrophy with rather interesting findings. In the lumbar enlargement of the cord there had been found a distinct cavity extending for several inches. In the dorsal segment was a large gliomatous mass pressing upon the cord. This was apparently a lesion independent of the disease in question. He was in a position to agree entirely with Dr. Wiener as to the beneficial effect of exercise. He had tried systematic exercise in those affected early in life, and had not found the slightest benefit from carefully conducted exercises of this kind carried on for a considerable time.

Dr. B. Onuf said that the muscles which have to do the most work were the ones most affected; the muscles which must bear the weight of the body are the first ones to become affected. It was because of this fact that he had been led to try the effect of the opposite plan of treatment, *i.e.*, rest in bed. However, the result had been disappointing.

Dr. Collins said that the postmortem examination referred to by Dr. Hammond had been on a patient that had been under his own observation for over two years. This man had been twenty-four years of age at the time of his death, and the disease had existed for fourteen years. Careful investigation into the family history had shown no similar case. Up to his eleventh year he had been free from all disease. For eleven years he had been unable to walk, and for eight years had been bedridden. Up to a short time before death he had retained the ability to move his finger though he could not move his arm, and his facial muscles continued to act well. It was almost typical case of progressive muscular dystrophy. Death had resulted from a tuberculous

infection. The brain reported on by Dr. Sachs had been from a boy under his observation for six or seven years. Assiduous attention to calisthenic exercises had made him worse in proportion to the assiduity, and that too although he had had an excellent calisthenic teacher. This had been Dr. Collins' experience in all other cases in which the disease had begun early in life. The changes described by Dr. Brooks as having taken place in the ganglion cells certainly opposed one's ideas of the relation of the neuron to disease. After five years' experience with the Nissl stain he felt in a position to assert positively that nuclear eccentricity means absolutely nothing.

Dr. Smith Ely Jelliffe said that he had heard nothing said by Dr. Brooks about the terminal end plate of the motor nerve.

Dr. Brooks replied that after attempting to study end plates he had come to the conclusion that this could only be done with methylene blue during life, and that he had been unable to do. He could not tell Dr. Dana why the connective tissue should grow up so much more in one place than in another. In the calves there had been an increase in volume, and in the pectoral muscles a decrease. It was not improbable that it was due to some inflammatory or toxemic condition in these particular muscles, or possibly that the muscle had been over exercised. He agreed with Dr. Collins about the uncertainty of the Nissl stain, and that the findings described by him as having been observed in the ganglion cells were negative.

Dr. Sachs closed the discussion. He admitted that the findings reported in the paper certainly did tend to shock one's confidence in the neuron theory as a whole.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held March 15, 1901.

George R. Elliott, M.D., Chairman.

Infantile Spinal Paralysis.—Dr. Homer Gibney presented a boy, aged eleven years, who had had infantile spinal paralysis. There was equino-varus of the left foot with slight cavus. According to previous history, astragalectomy had been performed five years previously without beneficial results. November last Dr. Gibney exposed the tarsal bones, curetted the cartilages, sutured the wound and applied a plaster-of-Paris bandage. The result was that the foot was shown at a right angle with slight motion.

Acute Hip Disease.—A second patient, a girl six years of age, was shown by Dr. Gibney. She was suffering from acute hip disease when first seen in October, 1899. A brace was applied and the child put to bed. Her hip became worse; the hip was stretched and a plaster-of-Paris spica was applied. An abscess developed and was opened January, 1900. Improvement followed the incision, but owing to a profuse discharge, fever and loss of flesh, the hip was excised April, 1900. The child improved rapidly after the operation; a small sinus remained.

Paraplegia Complicating Spinal Caries.—Dr. Gibney presented a third patient, a girl nine years of age. She was admitted to hospital December, 1900, with the history that her disease followed an attack of diphtheria five years previously. A plaster-of-Paris jacket was worn for six weeks at onset of disease and then for eighteen months she wore a Taylor brace with head-rest attachment. In 1897 she had an attack of paraplegia which lasted six months. One year ago she had a second attack which persisted at the time of admission into the hospital. There was at that time paraplegia, incontinence of urine, increased reflexes with marked ankle clonus. December last the child was put to bed wearing a plaster-of-Paris jacket with head extension. The jacket was reapplied January, 1901, with head extension and plaster straps over the shoulders. A third jacket was applied February 21st. Improvement was gradual and child was shown with fairly good voluntary use of legs.

Dr. Royal Whitman said he hardly thought it fair to say that the paraplegia developed while under treatment by the Taylor brace. The child had come under his observation four years before with very slight deformity. The child was under poor control and had been through many hands, including osteopaths. Recently he had again seen her and referred her to the Hospital for Ruptured and Crippled. He would suggest that the case was one that illustrated ineffective treatment rather than mechanical treatment of any form.

Dr. Gibney said he simply showed the patient to demonstrate the effect of a well-applied apparatus. As a matter of fact, the paraplegia did develop while the child was wearing a Taylor brace, but was under no one's medical or surgical care. The brace was ill fitting, in fact worse than useless.

Coxa Vera.—Dr. W. R. Townsend presented a boy, fifteen years old, who came to the Hospital for Ruptured and Crippled one month ago, with the history that without any apparent cause one year previous he began to have difficulty in walking and was easily fatigued. The difficulty in locomotion had steadily increased. The limbs were equal in length and the X-ray revealed a very marked case of coxa vera. There was limitation of motion and the great trochanters were one inch above Nelaton's line. Limitation of motion, especially in flexion and extension, was very great. There was not over 15 degrees of motion on the right side and none on the left. Standing the knees could not be separated more than three inches. The patient sat with difficulty. A radiograph was

shown. He asked if any member of the Section had seen a case of coxa vera with so much limitation of motion.

Dr. Whitman said that limitations of flexion was always present in these cases, although limitation of abduction was the more marked feature. He stated that some years ago he had presented a patient before the Section with even more marked disability than the present one. In that case the deformity progressed until the patient was totally disabled. After the acute symptoms subsided he performed an osteotomy on one femur with so good a result that the operation for the lesser deformity was never made. The man finally recovered perfectly; motion returned as far as flexion and extension were concerned. He believed that operative treatment would completely relieve the condition.

Spondylose Rhizomelique.—Dr. Townsend presented a man, thirty-five years old, who five years ago began to have stiffness of the back and difficulty in walking. He had two attacks of muscular rheumatism. He had had no pain excepting in the upper part of the back and when sitting. These symptoms increased until the present time; he was obliged to use crutches. The thighs were flexed on the pelvis about 20 degrees; extension and flexion were much restricted. He regarded the lesion of the hip-joints and the spinal stiffness as typical of spondylose rhizomelique. He suggested a plaster-of-Paris jacket as of some service.

Dr. George R. Elliott said errors of diagnosis were not infrequently made and the disease mistaken for one of the varieties of chronic spinal rheumatism; frequently great spinal pain and hyperalgesia accompanied by the progress of the disease, subsiding after a while. He referred to a patient he had seen a few years ago, before the disease had been carefully described, whom he examined under an anesthetic owing to the great degree of pain present. The pain subsided after three or four years—the marked ankylosis so characteristic of the central type of the disease remaining. This patient was shown before the Neurological Society by Drs. Sachs and Fraenkel (Oct. 18, 1899).

Dr. Townsend showed two radiographs, one showing union of a fracture of the neck of the femur after use of a long traction hip-splint (patient shown before Section Jan. 11, 1901); the other radiograph was of a case of double dislocation of the hip-joint which had been treated by the bloodless reduction eight weeks before. The picture was taken through the plaster-of-Paris splint.

Congenital Clubfoot.—Dr. Judson presented a boy, five years old, first seen when there was marked and resistant typical double deformity which had been reduced by the painless continuous leverage of a simple brace applied with adhesive plaster and often removed for manipulation of the feet; later a walking brace had been used; all the apparatus used was of a common kind with a single invisible upright. The braces were made of tractable metal allowing change from the deformity to the normal and later to overcorrection. The feet followed these changes through force of adhesive plaster and later by body weight. At the age of fifteen months the deformity had disappeared. Treatment was resumed after seven months' interval the outer border of the feet having become slightly callous; walking braces were applied and worn for twenty-two months, finally laid aside January 15, 1900. On presentation the child walked and ran with normal ability and without defect in his gait. The only remaining defects were slightly shortened Achilles tendons, but these were slight as he could even walk on his heels. In this affection the following were to be considered as favorable elements: (1) The certainty of rapid growth; (2) the plastic or formative condition of the parts; (3) the absence of body weight for eighteen months; (4) the certain effect of continuous leverage; (5) the weight of the body applied on the right side of the plane between varus and valgus in virtue of which the child could stamp his foot straight; (6) the absence of necessity for haste; (7) use of tractable metal. An unfavorable point was the postponement of treatment till the child was two years old.

Dr. Whitman said he could not agree that Dr. Judson's case should be considered at all remarkable as to result; it was an average case and an average result. It was evident that there was still a slight tendency to varus dependent upon the slight equinus which still persisted. This, he thought, illustrated the weak point in Dr. Judson's scheme of treatment, that having overcorrected the varus deformity, he depended upon the weight of the body to overcome the residual equinus, whereas this deformity should be as thoroughly overcorrected during active treatment as the varus.

Dr. Judson replied that a further elaboration of the principles of continuous leverage would have secured a normal tendo Achillis and completely corrected the equinus; while the result was not absolutely perfect, he considered it as supporting the statement that an operation or violence was in this affection a confession of failure at some time in the history. In practice the resistance of tissues was one of the lesser difficulties to be overcome in the management of cases of this kind. Greater obstacles were unreasonable haste to see a result and mistaken reliance on rapid and easy methods.

Dr. Taylor regarded the result as very creditable, but did not think that all danger of a relapse was passed. He did not agree with several of Dr. Judson's statements which implied that operations were never indicated; operative treatment was often unsatisfactory, if not combined with and followed by mechanical treatment; each method had its proper field

and often both were needed. While himself inclining to conservatism, he considered Dr. Judson's remark in disparagement of operative interference much too sweeping.

Funnel Chest.—Dr. Judson presented a man, seventy-one years old, having a deformity which although rare, had been described by a number of observers. It was a curious malformation, entailing no great disability, of uncertain origin and calling for no treatment. From an angular projection at the junction of the manubrium and the gladiolus there was a continuous depression till the deepest place was reached at the end of the xiphoid appendix. The cartilages of the lower ribs were prominent, as usual, on each side and the front of the chest, although somewhat flat, was normal except for this funnel-like depression which began on each side at the nipple line and was cup-shaped at the bottom with a depth of 1½ in., unchanged by expiration (31 in.) or inspiration (34 in.). The man said he had always been so and had never known of another person similarly affected in his family. He had eighteen brothers and sisters. He had been fond of athletic sports in his youth, was a shoemaker by occupation and had enlisted in the military service in 1862. There was no history or sign of rickets or spinal disease. He had been free from notable diseases of the chest or otherwise, although years ago he had been told that he had serious chronic lung disease.

Dr. H. S. Stokes said it was difficult and frequently impossible to make a correct physical diagnosis when chest deformity existed. He cited a case of Pott's disease where the patient had been told four years ago that he had pulmonary tuberculosis and a bad prognosis had been made. He had frequently examined the sputum of this patient with negative results; all signs of lung involvement disappeared. He cited two cases of lateral spinal curvature which had lately come under his notice where errors of diagnosis had been made. In one the diagnosis of tubercular consolidation was made which turned out a slight bronchitis.

Poliomyelitis.—Dr. Myers presented a case of poliomyelitis in a boy, thirteen years old; the disease dated from early infancy; the case was exhibited to show the muscular changes—the right quadriceps was completely paralyzed and the right ligament patella was one inch long; the left quadriceps was fairly strong and the lig. patella 2¼ inches long. Osteotomy had been performed on the right side for a recurring genu valgum which had been caused by the greater power of the external hamstring muscle. The muscle was split and one-half transplanted and given to the internal hamstring and the knock knee did not occur. He called attention to the marked rotary lateral curvature of the whole dorsal spine with convexity to the left, the stronger side, while concavity was toward the side of paralysis of the lower extremity and erector spinal muscles. In clubfoot due to poliomyelitis, the shortening always occurred in the stronger or least paralyzed muscles: by analogy the erector spinæ muscles on this boy's left side, those least paralyzed should be contracted and they were. This drew the entire thorax strongly to the left and downward. To maintain his equilibrium the boy had thrown his head and shoulders to the right by voluntary effort inducing the form of curvature present.

Congenital Dislocation of Hip with Fracture of Shaft of Femur.—Dr. Elliott presented a five-months-old baby sent to him three weeks previously for diagnosis. He found dislocation of left hip and suspected fracture, both of which were confirmed by an X-ray picture. According to the history, birth of the child had been very difficult—the breech had presented and great difficulty had been experienced and instruments used. No difficulty was anticipated in reducing the dislocation; the fracture of the femur, however, complicated the matter. He said he proposed to attempt reduction under an anesthetic and, if any great difficulty presented itself, he would wait till later and do it by the Lorenz non-cutting method.

Congenital Dislocation of the Patella.—Dr. Elliott showed a patient, a young man twenty years old, with dislocation of the right patella. His relatives had told him that it was first noticed two days after his birth; he wore apparatus at various times, but nothing since 1888. The patella slipped into place on extension, but on flexion slid over the external condyle of the femur even if force was applied to hold it; there were two inches of atrophy of the right thigh; a slight degree of knock knee existed. All that the patient complained of was a sense of weakness and uncertainty of the leg. The patient wanted to know if the condition could be remedied without leaving him with a stiff knee. He preferred his present condition of slight disability to a stiff leg.

Case of Spondylolysthesis.—Dr. Taylor presented a man, nineteen years old, whose occupation was loading and unloading furniture. Last December he sought treatment for weakness of his back and occasional pains in the lumbar region at night, after hard work. About three years ago he slipped on the ice and fell heavily on the buttocks. He worked the following day. He experienced no inconvenience for some time, but within a few weeks he noticed a decided projection of the lower part of the spine, which he still has. He thinks it is less now than formerly. Examination revealed a marked projection of the fifth lumbar spine and a deep depression above it. At the bottom of this depression could be felt the fourth lumbar vertebral spine one-half inch in front of its normal position. The patient could bend forward and touch the floor and showed none of the characteristic attitudes of the rigidity of spondylitis. He was strong and able to work. There was no rectal nor bladder symptoms and no lower extremity paralysis.

THE STUDY OF INTERNAL MEDICINE.[1]

BY WILLIAM OSLER, M.D.

OF BALTIMORE;

PROFESSOR OF PRACTICE OF MEDICINE IN JOHNS HOPKINS UNIVERSITY.

How shall a young man prepare himself to rise in the medical profession to a position in which his brethren lean upon his judgment and rely upon his decisions; and what steps shall he take to become as competent to wrestle with disease as those who have made their names famous in the near past, such men as Hosack, James Jackson, Daniel Drake, Swett, Alonzo Clark, Austin Flint, Henry I. Bowditch and Fordyce Barker?

At the end of the first quarter of this century there will have arisen a new set of consultants, the leaders of thought and the exponents of experience in internal medicine who will have come from the ranks of the college and hospital graduates of to-day. The question that each of these ambitious youths is now asking himself is, "How can I make my work worthy of the reputation I desire?"

Before laying down the general lines of work, that if faithfully followed may bring ultimate success it might be well to remind the anxious youth that the fame of a prominent consultant at sixty is ofttimes accompanied by a treadmill routine of work and a never-ceasing weight of responsibility that makes him look back to the days of his freedom when he could follow his bent untrammelled and undisturbed with as much envy as he formerly looked forward to the days of his reputation. Joy comes in the climbing, and while living laborious days, happy in the growing recognition that he is receiving from his colleagues the young physician is realizing the best that the profession has to give.

The first decision to be made is whether or not to go abroad. It is not necessary, but it is very helpful. It gives a physician a broader foundation on which to build and a year or two in the laboratories and clinics of Europe enlarges his capacity for appreciation. To walk the wards of the famous hospitals and put in a few quiet months of study in one of the German universities will store his mind with priceless treasures, and will do more than anything else to free him from the fetters of his own opinions, and help him escape the besetting sin of most young physicians, that intolerant attitude of criticism toward everything outside of his own circle and his own school.

But he need by no means remain narrow-minded, nor lack perspective in his views if he cannot afford the time and money for a year abroad. Some of the ablest men in the profession have found their opportunities in country practice and have built up wide reputations in small towns. But if the Continent is denied him by all means let him seek the opportunities afforded to him in this country and as early as possible get the breadth of view that comes only by observation and comparison of the various methods of accomplishing the same ends. If he lives in a small city or provincial neighborhood let him make a great effort to spend a few weeks each year in Boston, Philadelphia, Chicago, New York or Baltimore, visiting hospitals and clinics and meeting the men in their societies. If he lives in one of the large cities let him by no means feel that he has all that may be acquired at his command. Short vacations spent in visiting different universities and hospitals from the Chesapeake to the St. Lawrence will stimulate to new ideas, and give him that combination of conservatism and independence that comes only with travel.

This is for his youth when the problem of ways and means is all important. But it should be but the incentive to save for further travel and study. At the end of a few years when he needs a rest and change let him invest $600 in a summer semester in Germany working quietly at one of the smaller universities and absorbing the spirit of patient investigation that is the genius of the German mind. Another year let him spend three months in Paris; lay schemes in advance and it is surprising how often the circumstances will fit them.

Poll the successful consulting physicians of this country to-day, and you will find they have been evolved either from general practice or from laboratory and clinical work; many of the most prominent having risen from the ranks of general practitioners. I once heard an eminent consultant rise in wrath because some one had made a remark reflecting upon this class. He declared that no single part of his professional experience had been of such value. But I wish to speak here of the training of men who start with the object of becoming pure physicians. From the vantage ground of more than forty years of hard work, Sir Andrew Clark told me that he had striven ten years for bread, ten years for bread and butter, and twenty years for cakes and ale; and this is really a very good partition of the life of the student of internal medicine, of some at least, since all do not reach the last stage.

But how shall the young man gain even his

[1] In part a résumé of an address on "Internal Medicine as a Vocation," delivered at the New York Academy of Medicine.

dry bread during the first few years of his professional career? By picking up the crumbs that fall from the practice of the older men who can always put something in the hands of an able youngster, by fees from classes, journal work, private instruction, work from the schools, night work, surplus work in busy seasons, by taking poor or chronic patients that the older man cannot spare time to attend, by keeping office hours for the scanty summer practice of the wealthy physician who is taking his holiday; in short by taking every sort of medical practice that comes to hand, for to see disease is the main thing and a man must be willing to treat disease where he can find it, even though he barely ekes out a living while he is gaining his experience. He should stick closely to the dispensaries, for a first-class reputation may be built up in them that will pay in later days and will bring experience that can be gained in no other way. In the meantime these will afford valuable material for papers for medical societies and for publication in scientific journals. But the young physician should be careful how and where he writes, placing himself under the guidance of his seniors and endeavoring to do a little careful work that is needed in some particular branch, instead of attempting anything that is startlingly original. Byron Bramwell collected most of the material for his Atlas of Medicine while he was an assistant physician in the Royal Infirmary, Edinburgh. Many of the best men in London have served from ten to twenty years in out-patient departments before getting wards. In this country long and faithful service in a hospital dispensary is not necessarily awarded by any position of honor or influence on the hospital staff, but the experience and the reputation and the fraternal relations are invaluable. Once established as a clinical assistant a young man has the material with which to work out his own education.

There are three lines of work which he may follow, all of the most intense interest, all of the greatest value to him—chemistry, physiology, and morbid anatomy. Professional chemists look askance at physiological chemistry, and physiological chemists criticize pretty sharply the work of some clinical chemists, but there can be no doubt of the value to the physician of a very thorough training in methods and ways of organic chemistry. We sorely want in this country, men of this line of training, and the outlook for them has never before been so bright. If at the start he has not had a good chemical training, the other lines should be more closely followed.

Physiology, which for him will mean very largely experimental therapeutics and experimental pathology, will open a wider view and render possible a deeper grasp of the problems of disease. To Traube and men of his stamp, the physiological clinicians, this generation owes much more than to the chemical or postmortem-room group. The training is more difficult to get, and nowadays when physiology is cultivated as a specialty few physicians will graduate into clinical medicine directly from the laboratory. On the other hand, the opportunities for work are now more numerous, and the training which a young fellow gets in a laboratory controlled by a pure physiologist will help to give that scientific impress, which is only enduring when early received. A thorough chemical training and a complete equipment in methods of experimental research are less often met with in the clinical physician than a good practical knowledge of morbid anatomy, and, if our prospective consultant has to limit his work, chemistry and physiology should yield to the claims of the dead-house. In this dry-bread period he should see autopsies daily, if possible. Successful knowledge of the infinite variations of disease can only be obtained by a prolonged study of morbid anatomy. Of special value in training the physician in diagnosis, it also enables him to correct his mistakes, and, if he reads its lessons aright, it may serve to keep him humble.

It would be folly to suppose that every bright and energetic young physician can attain that widest of reputations in which his name becomes familiar to the laity of this continent and to the profession of Europe. That is not the point he is striving for, and should he attain it he would find himself at the mercy of an exacting public with an enormous and irksome practice, and not time to keep abreast of, and much less lead the thought of the times. A professional reputation in even a restricted area affords an excellent income and a satisfactory life-work to those who care to be masters of their own fate and not public slaves. With the present overcrowding of the large cities and the keen competition among physicians the tendency will be more and more to drive the younger men into the small towns which have hitherto sent their best talent to the city and received no adequate return. There are throughout the country hundreds of small hospitals whose clinical opportunities are wasted for lack of younger men who will do with their might whatsoever their hands find to do. These are well worth the consideration of the graduates who are just ready to begin their practice and who realize that to settle in one of the large cities means a desperate struggle for a livelihood. With capital or the promised coöperation of a well-established physician, or with a grim bulldog tenacity the young doctor can live through the educational years of his practice and begin to reap the benefits in the forties. But for the young man whose only capital is brains and whose only backing is his belief in his own powers of work the same town affords an opportunity to do work that is just as valuable to the community and to build up a reputation that is of far more help to his professional brethren than the reputations of the far-away great consultants.

To any young man who is just starting the practice of medicine in a town, say of 40,000 to 50,000 inhabitants, and whose ambition it is to work up a consultant practice, I would say, "If

you have brains and staying powers and can avoid entanglements you will probably succeed; but to do so you must make your position by hard work, courteous manners and a close study of human nature. Say to those that ask that you intend to practise medicine only and will not take surgical and obstetrical cases. If you have an opportunity to work in a dispensary or to do any teaching, take the opportunity gladly and give full measure. Your services may be of help in the local hospital. A little blood work or pathological or microscopical examinations, if done voluntarily in a modest grateful spirit, may win you an opening to assist some of the house physicians in his ward work, but in this case be careful that you do not scintillate before the staff in the glory of your recently-acquired knowledge. It will be enough to be in the right occasionally without calling attention to the fact. Get your own little clinical laboratory in order and do not try to impress the physicians who call upon you with your very up-to-date equipment. Remember that they have brought a generation into the world and kept it in health, they have staunch friends and rich patients and are ready to take you into their fraternity if you are civil and modest. Join the city and county societies and never miss a meeting, but keep your mouth shut for a few years, particularly in the discussions; read the journals, but do not discuss the new books before you are grounded in the old ones.

At the end of twenty years, when about forty-five years of age, the man who has worked wisely and well should have a first-class reputation in the profession and a large circle of friends and patients. He will probably have precious little capital in the bank, but a very large accumulation of interest bearing funds in his brain pan. He will have gathered a stock of special knowledge which his friends in the profession appreciate, and they will begin to seek his counsel in doubtful cases and gradually to lean upon him in times of trial. He may awake some day, perhaps quite suddenly, to find that twenty years of quiet work, done for the love of it, has a very solid value.

THE RELATION OF THE STUDENT OF MEDICINE AND THE RECENT GRADUATE TO THE FIELD OF SURGERY.

BY GEORGE RYERSON FOWLER, M.D.,
OF BROOKLYN, NEW YORK;
SURGEON TO THE METHODIST EPISCOPAL HOSPITAL; SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL; SENIOR SURGEON TO THE GERMAN HOSPITAL.

It is a noticeable fact that the majority of medical students commence rather early in their student career to evince a fondness for surgery. This is partly due to the glamor and intensely dramatic surroundings of the surgical clinic which appeal to the sensibilities and susceptibilities of their yet undeveloped professional minds; partly to the old traditional, and yet in great measure unfounded, want of certainty attending the therapeutic effects of drugs, and the supposed certainty of results following a surgical operation; and finally, to the belief that, in the field of surgery the larger opportunity is offered for the application of the anatomical knowledge the gaining of which forms so large a portion of their work in the early part of the college curriculum.

As the field of study broadens before the student of medicine, and his mind undergoes those evolutionary changes incident to the grasping of new phases of the healing art, the narrow mindedness which, in the beginning prompted him to envy the surgeon the supposed éclat of his surroundings progressively diminishes, until finally, between the admiration excited for the acumen of the skilled medical diagnostician, and the zeal and solicitude essential to the conscientious discharge of the duties of the obstetrician, he wavers, and finally, if he is faithful in his work and earnest in his desire to equip himself for his lifework, he will endeavor to store his mind with every available item of knowledge to be gleaned from lectures, demonstrations, clinics, reading, and dissecting-room and laboratory work.

Should the fondness for the surgical still cling, however, in spite of the awakening of admiration for the great minds which are constantly developing new facts, or advancing fresh theories in the other branches, he will realize that the surgeon, after all, is but an accomplished physician with a trained hand and a readiness to employ mechanical resources in special conditions. The fact becomes more and more impressed upon him that, in the field of surgery, a full and complete knowledge of all of the resources of the medical art are essential to the successful practice of this branch. He no longer looks forth upon a great barren waste with one bright oasis toward which he must make a short cut; but rather he gazes upon broad and richly cultivated fields of thought, each one of which invites him to linger and taste of the inspiration of its well-spring, and enjoy its intellectual repasts.

When he has reached this stage, if the old ambition still prompts him and he feels that he must accomplish the ideal of his early student days, with a full realization of the conditions of the environment of the surgeon he will no longer aim to reach the goal by a straight path with sharply-defined boundaries, but, on the contrary, he will make excursions in each of the fields that opportunity throws in his way, with the well-grounded belief that these will, in time, furnish him with additional incentive for endeavor, supply him with fresh food for thought, and, in addition, increase his equipment for his work as a surgeon.

Upon graduation day he steps in the midst of the workers. The time has come when he must join them. His mind is still fixed upon working in the field of the surgeons. How can he best gain that further knowledge which will

enable him to range himself side by side with the Astley Coopers and Valentine Motts of his earlier day-dreams? Surely not by casting aside four-fifths of the equipment of which he is already possessed in the endeavor to gain the trained hand and mechanical skill of the surgeon of his boyish imagination. That were indeed a profligate course; he cannot afford to relinquish his hold upon any of the knowledge gained in order to grasp what, after all, may be to him but a shadow. He must hold fast to that which he has gained, for it is his main dependence; the ground-work and foundation of that superstructure he hopes to build. But knowledge, to remain fresh and available, must be put to use, and thus become in time part and parcel of his being. How shall he put it to use in order that it may be firmly engrafted and come to bear fruit?

Two courses are open to him in order that he may make practical use of the knowledge already gained, in order to conserve it for future use by strengthening its all-too-precarious hold in the soil of his mind, by the lessons of experience. He may enter at first the field of general medicine, where opportunities occur here and there, through the diversified character of the work which will come to him, for the application of the surgical portion of the teaching of his student life. But he will soon realize that, although many cases in the field of internal medicine will come to him which will possess no interest from the surgical standpoint, the surgical cases will be few and far between. But of these the greatest rarity will be a case which has no interest from the purely medical standpoint. But art is long and time is fleeting. Exceptionally there may fall in his way, through the rapid building up of a large *clientèle,* opportunities for doing surgical work to the extent of increasing his self-confidence, and if he is wise he will endeavor to supplement this by practising operations upon animals. Later on he will be justified in relinquishing the work in internal medicine that comes to him to others and devoting a larger share of his time to the cultivation of the surgical branch. But the transition must be gradual; advances cannot be made by leaps and bounds. He must increase his store of knowledge in every branch of professional work while at the same time he is training his hand and cultivating mechanical skill.

The mere fact that he turns away medical work in order to pay more attention to his surgical cases will cause the latter class of work to gravitate to him, and this circumstance will also increase the confidence of his fellow practitioners in his earnestness as well as honesty of purpose. This confidence will prove, in the long run, the most important factor in his success as a surgeon, and will naturally result in a demand for his services as a consultant, as well as his selection for a position upon the surgical staff of some hospital. While the attainment of the latter will be a most desirable incident of his life, for by means of it he will find larger opportunities for the exercise of his surgical skill, yet he will do well to remember that he should only seek such promotion by deserving it; other than this the position should always seek the man.

While financial considerations may compel him to follow the course above outlined, he may well feel that it is not the best. The other course is to enter the competitive examination for an interneship in some large hospital, and there win his way to a field in which he may work with the greatest possible advantage from any standpoint. A hospital in which he may serve both as a medical and surgical interne will be found to offer him the best opportunities. Here, while he will be thrown to a certain extent upon his own resources of knowledge, at the same time he will be brought in contact with men of large experience, both in the medical and surgical branches of the profession. The medical service will serve the same purpose as an experience in private practice, with the additional advantage that this experience will have been gained in a much shorter space of time, and under proper guidance, thus greatly enhancing its value. At the same time he will be brought into contact with the surgical work of the hospital, if only in a minor capacity. In any event he may be an onlooker in relation to surgical matters while serving as a medical interne, and even this has its advantages. It is probable, however, that he will take a more or less active part in the emergency surgical work, at least. In hospitals in which the professional organization is such that it is intended that the internes should familiarize themselves with the hospital work by such rotation in service as shall give them a subordinate position in first one service and then the other, becoming house physician before becoming house surgeon, the best advantages are gained for the internes themselves.

When the position of house surgeon has been gained the opportunity of the man, who has surgical aspirations and who has endeavored in every way to live up to the preparatory requirements, has arrived, and he will lose no chance of availing himself of it to the utmost. Here he becomes one of the direct assistants and co-workers of the masters in the art in which he is endeavoring to perfect himself. By his quickness in adapting himself to the exigencies in the operating-room he will inspire confidence on the part of his chief, and by this and his intelligent care of the cases in the surgical wards he will be entrusted with a share of operative work and the more or less complete control of the after-treatment. This will prove a most valuable aid to him, not only in the experience actually gained, but in the self-confidence inspired.

A trained hand will be developed in such actual manipulative work as will be assigned to him, from the holding of a retractor and sponging to the clamping and tying of vessels. Mechanical skill comes with the application of fixed dressings and apparatus. The permission now and then from his chief to operate upon emergency cases, the number of these depending upon the confidence inspired by his behavior while assisting, all go a long way toward making him a trustworthy surgeon.

With the termination of his hospital service his chief may have become so impressed with his availability as an assistant as to place him in the way of becoming a regular assistant at the hospital clinic. If the work in the hospital has been such as to give opportunities for acquiring practical knowledge in the bacteriological and pathological laboratory, so much the better. If not he should seek to supply this deficiency, for he has now come to the point when he must put on the finishing touches, so to speak, of a preparation which, while it does not make a surgeon of him, is designed to teach him how he may become a surgeon. He will now spend a year in the practical work of some pathological institute, either at home or abroad. If he has a taste for foreign languages, and has already acquired some knowledge of German or French, he may spend this time profitably either in Berlin or Vienna, or in Paris. The constantly increasing facilities for following up the work in our own country, however, are such as to make it extremely profitable for him to pursue his studies here, particularly if his knowledge of languages is limited to English. Or, if he is desirous of combining his studies in this line with a residence abroad for a time, he will find excellent opportunities in London. If he has followed up his work as an interne closely he will have felt the need of more knowledge of surgical pathology and bacteriology, and will enter upon this portion of his work with increased zeal and enthusiasm.

The final culmination of his efforts to prepare himself for surgical work will be the securing of a place in the service of a hospital surgeon as an assistant, in which position a decade may be spent with profit. As time goes on he will be entrusted more and more with important surgical work. In the very nature of things vacancies must occur upon the surgical staff of the hospital with which his chief is connected, in which case he will have made himself so necessary to the work of the institution that his promotion will follow as a matter of course. During this decade of his life no opportunity must be lost of gaining knowledge of most approved methods, not only as these develop in the work as done by his chief, but by a close study of current surgical literature, and watching, as opportunity offers, the work of other surgeons. An occasional visit to the surgical clinics of the medical centers of this country, as well as those abroad, forms a very profitable and at the same time enjoyable way of taking short vacations to the aspirant for surgical honors.

Above all things he should not fail to form habits of systematizing his knowledge, and of practising self-criticism. A faithful record of work done and a judicious selection of this for publication are of inestimable value. This will bring him work to do on his own account, and at the same time enrich the literature of his profession. While some practice will come to him through his chief, more will come from other sources. Likewise a recognition of the character of his work from outside the institution in which he works with his chief may, and frequently does lead to a consideration of his eligibility for appointment in some other hospital as attending surgeon. He will lose nothing, however, but on the contrary will be largely the gainer by a consistent loyalty to the chief who recognized his ambition and made it possible for him to become a surgeon.

At last he is a worker in the field of surgery. He may or may not become the originator of difficult or brilliant surgical procedures, but if he attains to good judgment, as based upon a cultivation of powers of observation and proper discrimination, combined with the experience which will certainly come to him, he will be trusted by his colleagues. When the profession trusts him, the public will have confidence in him, and when these have been reached he will have become a surgeon.

THE MEDICAL MAN IN THE NAVY.

BY W. K. VAN REYPEN, M.D.,

SURGEON-GENERAL OF THE UNITED STATES NAVY.

The Medical Corps of the Navy is recruited directly from civil life. Any man who is a citizen of the United States and between twenty-one and thirty years of age can obtain the permit to appear before a Naval Medical Examining Board by making application in the prescribed form and submitting at the same time suitable certificates from persons of good repute, testifying from personal knowledge as to his good habits, moral character, and citizenship.

Recognizing the responsibilities of the men chosen to safeguard the health of the personnel of this rapidly growing and very important branch of the public service, and the necessity for ability in the treatment of disease and injury, the Government has wisely made the test for admission to this Corps one simply of merit, eliminating political and other influences and conferring the privileges of a commission in the Medical Corps upon any citizen of the United States within the limitations of age specified and having those requirements neces-

sary for the successful practice of the medical profession under the flag afloat.

With this end in view, the Navy Department has adopted simple methods that all proper candidates, from whatever part of our country, may easily obtain the desired examination at any time and be impartially considered by a board of officers composed of members of the Corps desirous of affording every opportunity for the exhibition of those qualities of body and mind which are necessary for a useful naval life. For this purpose two Examining Boards are kept constantly organized—one at the Naval Laboratory and Department of Instruction, Brooklyn, N. Y., and the other at the Naval Hospital, Mare Island, California. Both of these boards conduct the examination in accordance with instructions issued by the Surgeon-General of the Navy, who also willingly sends to any person making application an official circular containing such information as may be necessary for his guidance.

Each Board is composed of three medical men who, while impressed with the importance of the duty assigned them and required under oath, to report on the physical, mental, moral and professional qualifications of each candidate, recognize the defects in all systems of examination for the proper appraisement of mental value and, therefore, endeavor to conduct the candidate in a simple and practical way over ground that should be very familiar to him if he has been a reasonably honest student of medicine and has exercised judgment and discretion in his work. Indeed the Board does not object to being led by the candidate to a certain extent in some directions in which the natural bent of his mind may have carried him, for it is the individual who is being appraised rather than the system of examination.

The order of examination is as follows: (1) Physical. (2) Written. (3) Oral. (4) Clinical. (5) Practical.

1. The physical examination is necessarily thorough, for the candidate is seeking a position which he usually desires to hold for life. The question involved is, however, not simply one relating to probable length of life, but more especially to continued physical ability to perform duty, for an officer is paid when sick and, when permanently incapitated for active naval service on account of physical disability, has the privileges of the Retired List, where, if his disability has been an incident of service, or his retirement is on account of age, he receives as much as seventy-five per cent. of the pay at sea. This is a very important consideration in connection with the subject of pay in the Navy, for, while the following table designates the various grades of the Medical Corps and the pay received in each grade, it should be regarded in relation to the provisions for retirement for disability, or for age, 62 being the limit of age on the Active List.

PAY TABLE.

	At Sea.	On Shore.	Allowances per Annum.[2]
Assistant Surgeons:			
Rank of Lieutenant (junior grade)[1].	$1,650.00	$1,402.50	$288.00
Passed Assistant Surgeons:			
Rank of Lieutenant (junior grade)..	1,650.00	1,402.50	288.00
After five years in the Service	1,800.00	1,530.00	288.00
Rank of Lieutenant.....	1,980.00	1,683.00	432.00

2. In the written examination the candidate is required to address a letter to the Board of Examiners, stating the date and place of his birth; the school or college at which he received his general education; the medical school or schools at which he received instruction, and, if an alumnus, the date of his graduation, and the time when he commenced the study of medicine, also the titles of the textbooks studied; the opportunities he has had in engaging in the practice of his profession; and whether he has or has not been a resident physician or inferne in a hospital. To this letter the candidate appends his name in full, postoffice address, and his local address at the time of the examination.

He next prepares a thesis or short essay (without reference to notes or books) upon some professional subject indicated by the Board, and then makes written answers to questions on the usual professional subjects, including hygiene and quarantine, and on the usual general educational branches.

3. The oral examination is upon general educational subjects and the usual professional branches, including hygiene and microscopy.

4. The clinical examination of patients is made at a naval hospital and includes the use of the microscope, thermometer, laryngoscope, ophthalmoscope, and other aids to physical diagnosis. A written report is then made on one or more cases.

5. The practical examination comprises surgical operations on the cadaver, the applica-

[1] Designations of rank in the Navy differ from those employed in the Army. Lieutenant (junior grade), Lieutenant, Lieutenant-Commander, Commander, Captain, and Rear-Admiral, correspond respectively with the following ranks in the Army: First Lieutenant, Captain, Major, Lieutenant-Colonel, Colonel, and Brigadier-General.

[2] Only when quarters are not furnished by the Government. There is also an allowance of eight cents a mile to officers traveling under orders.

tion of splints, bandages, and surgical dressings, the use of the microscope (for clinical purposes and the recognition of pathological and other specimens), and chemical and pharmaceutical manipulations.

With reference to the amount of general education considered necessary by the Board it should be considered that all naval officers are representatives of their country in other lands, where a welcome is extended to them by representative people. The social life of a Medical Officer of the Navy is also regarded in relation to members of the other naval corps who are assembled on each ship and station and with whom the medical man in the Navy is associated in various duties and necessarily more or less intimately in every-day life. Apart, therefore, from the usual consideration that a medical education should rest upon the foundation of a fair general education, it is apparent that a medical officer of the Navy should for many other reasons be a well-educated physician.

The Board recognizes the necessity for this requirement, but, avoiding all extremes, seeks simply to maintain such a standard in the Corps that its members may be regarded worthy of attention not only professionally, but also from the general educational point of view, considering that in naval as in civil life both are of mutual assistance and more or less necessary for a reasonable success. The examination in that direction is, therefore, carried only sufficiently far to determine whether the candidate could maintain the general position advisable for a successful life as a medical man in the Navy. Of course, however, if the applicant seeks credit for advanced work on general educational subjects, opportunity is afforded him to obtain the additional credit.

The application for permission to appear before the Board must be in the handwriting of the applicant and addressed to the Honorable Secretary of the Navy. The form of application is as follows:

.....

.....190

Sir: I request permission to be examined for an appointment as Assistant Surgeon in the United States Navy.

I was born at ....., and was ..... years of age on the .....day of ....., 190, and am a citizen of the United States, residing in ....., county of ....., in the State of .....

I enclose herewith certificates as to moral character, habits, and citizenship.

Very respectfully,

.....

The Honorable SECRETARY OF THE NAVY,
Navy Department, Washington, D. C.

When in reply to this application the candidate receives a permit he is expected to notify the President of the Board, before which he is authorized to appear, of that fact and request to have a date fixed for the examination. He is also expected to present to the Board testimonials of educational and professional fitness. No allowance is made for the expenses of persons undergoing examination, which, if uninterrupted, is usually completed within ten days. A candidate may withdraw at any period of the examination, with the consent of the Board, and may, at a future time, present himself for reexamination.

The examination is not conducted in classes though several candidates may be before the Board at the same time. It is not therefore usually competitive in any sense but when two or more applicants happen to be awaiting appointment at the same time the commissions are conferred in the order of merit reported by the Board. After a successful examination appointment as Assistant Surgeon is made without delay for, though the membership of the Corps is limited by law and no such appointments can be made except to fill vacancies, there are as a matter of fact always some vacancies. This is especially prominent at this time, for the number of members allowed the Corps has been recently increased by act of Congress, owing to the rapid increase of the Navy and consequently the growing importance of this branch of the service. As a result there are now fifteen vacancies in the Medical Corps which with recent legislation favorable to the Corps and the advantages incident to a commission in the service afford opportunities for successful professional careers.

The order of appointment is of considerable consequence in a Corps in which the number in most of the grades is limited, with vacancies in those grades filled in the order of seniority after the physical and professional examination required by law. It is, therefore, of value to the applicant for admission to the Corps to appear before the Board at the earliest practicable date, as, if successful, he thus secures a higher place on the list, becoming senior to those subsequently appointed.

While promotion from one grade to another is, as a rule, to fill a vacancy in the upper grade caused by death, or retirement for age or disability, there is a very important exception in the entrance grade, that of Assistant Surgeon, from which promotion, after successful examination, is assured at the end of three years, the Assistant Surgeon becoming a Passed Assistant Surgeon.

The rank of an assistant surgeon is that of lieutenant (junior grade)—a naval rank corresponding with first lieutenant in the Army. This rank conferred upon the medical man in the Navy at the start is the result of recent legislation and represents a most important advance, making the Corps much more attractive and desirable, as the increase in rank carries with it an increase in pay and also removes the old objections to the life of an assistant surgeon which caused more or less discontent and acted as a deterrent to some in civil life who would otherwise have eagerly sought admission to the Corps.

The lowest commissioned rank in the Navy is that of ensign, corresponding with that of second lieutenant in the Army. This is the rank which an officer in the Line attains after six years' service—four years at the Naval Academy and two years at sea. Formerly an assistant surgeon entered with that rank and thus by regulation was placed in the junior officers' quarters. Now, entering with the higher rank, he becomes at once a senior officer—a wardroom officer with all the privileges incident thereto, including quarters to himself. This makes possible the privacy and comforts so valuable and desirable in life while afloat, and places the medical officer from the commencement of his career in a position consonant with his age, habits of thought, and responsibilities.

The old days have passed and there is a new era in naval medical life at a time when there is a new Navy, increasing each year in men and ships. No branch of the public service of our country has a more glorious and consistent history than the Navy and there is no branch which confers as a heritage greater distinction upon its members. The only way in which a future as great or greater can be secured is by as great or greater merit, and that this should be the test for admission to the Medical Corps should be regarded with favor by all who consider themselves worthy, as it ensures a Corps that honors and provides an incentive to achieve distinction within it; for, in the naval community as in others there are individuals differing in standing and some who make more of professional and other opportunities than others.

The conditions of naval life include travel at home and abroad, with a period at sea and a period on shore in one's own country, with duty in the various naval hospitals or at the different shore stations. When afloat one becomes familiar with foreign countries and diverse peoples, and acquires in time that wide education generally regarded as incident to travel. Steam has shortened the time between ports and thus relieved naval life of much of the monotony of former days. The opportunities have increased for a personal acquaintance with the diseases of different climates and the methods employed in medicine and surgery by medical men of different nationalities. In military surgery there have been at times opportunities for work apart from naval service, as when the medical officers of ships of various nations established a temporary hospital on shore to care for the wounded of both contending parties in a country the subject of revolution.

While at first the change from civil to naval life may be somewhat confusing, in time there is a recognition that it has brought its own peculiar problems from a professional point of view which require special thought and training. The routine of the naval medical officer's life includes not only the treatment of disease and injury, at times under unusual circumstances and without professional aid or advice, but also involves questions of the care of wounded in battle with transportation on board ships differing in construction; unusual hygienic problems of great importance; a thorough acquaintance with the state of health in the selection of recruits; and a knowledge of the seafaring mind and conditions of life at sea in connection with their relation to disease and perhaps to malingering in its various degrees.

These are in a broad way some of the various lines of medical work, the ever-changing conditions, the ever-changing surroundings at sea, different ports and different cities with varying influences stimulating medical observation primarily with a view to the care of men under supervision; for a ship of the Navy is a floating fort crowded with men, and the medical mind in its own department has opportunities for a wide range in human experiences and no small share in the responsibilities of life.

And so in view of all the circumstances it seems very just and proper that the commission signed and conferred by the President of the United States reads in part as follows:

"Know Ye, that reposing special Trust and Confidence in the Patriotism, Valour, Fidelity and Abilities of ....., I have nominated, and by and with the advice and consent of the Senate, do appoint him an Assistant Surgeon in the Navy with the rank of Lieutenant Junior Grade, from the ..... day of .....190 , in the service of the United States."

THE MUNICIPAL HEALTH DEPARTMENT SYSTEM, AND MORE ESPECIALLY IN REFERENCE TO ITS ADVANTAGES AND DISADVANTAGES AS AN OPENING FOR THE YOUNG MEDICAL GRADUATE.[1]

BY ARTHUR R. GUERARD, M.D.,

OF NEW YORK;

ASSISTANT BACTERIOLOGIST OF THE NEW YORK CITY DEPARTMENT OF HEALTH, AND INSTRUCTOR OF MATERIA MEDICA AND THERAPEUTICS IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Modern sanitary science and preventive medicine are slowly, but surely reducing not only the mortality from, but also the prevalence of, disease. This is a fact which cannot be denied; it is proven by the official records of vital statistics, and is apparently evidenced no less by the waning private practice of physicians. In former times four-fifths of all deaths and a corresponding number of diseases were due to preventable causes; but

[1] In the compilation of this article I have made liberal use of the excellent addresses by H. M. Biggs, M.D., on "Preventive Medicine in the City of New York" (1897), and "Sanitary Science, the Medical Profession, and the Public" (1898), as well as of the official reports of the New York City Department of Health.

now, owing to the general adoption of improved methods of hygiene, both public and personal, the death-rate and, at the same time, the frequency of sickness have been reduced to one-quarter of what they once were, and although much remains to be done in this direction, there is little doubt but that in the present generation we shall see a still further reduction of distinctly preventable diseases of at least one-third more.

The consideration of this fact, together with another equally as manifest, namely that of increasing competition in the art of healing, not only within the ranks of the regular medical profession along with its adjuncts the hospitals, dispensaries and clinics, but also outside the profession with the quacks and charlatans, Divine-Healers, Faith-Healers, Christian-Scientists, Osteopaths, and other fashionable sects of that ilk, who, although not more numerous to-day perhaps than in times past, still count their votaries by the thousands: I say that the contemplation of these indisputable facts may well make us pause, old as well as young medical graduates, and ask wonderingly, what are the chances of success in the practice of legitimate medicine?

Of course, in writing of the "chances of success," it is not intended to imply the accumulation of wealth, for it stands to reason, now as ever, that no man is fitted for the study of medicine who expects to grow rich through its practice. Such a one is by nature a merchant and should go into trade; and luckily, both for the good of the calling in general and for that of practitioners individually, the mercenary spirit is comparatively rare in the medical profession, inasmuch as this class of men usually find out very soon after graduation that medicine, like virtue, often is its own reward, and look for other and more lucrative employment. Neither is it meant to include physicians possessed of private incomes who are independent of their profession, and who while "waiting for a practice" may advantageously employ their unlimited spare time in attending hospitals and clinics at home or abroad, and in the acquisition of skill and experience, in the various specialties of medicine and surgery, although they receive no remuneration for their labors. Nor is reference made to the country doctor, who prefers to "lead the even tenor of his way" (thus wisely choosing perhaps) as a practitioner in the rural districts, where, though the financial prospects may not be brilliant, better opportunities are not infrequently afforded for an immediate return for medical service.

But granted that our young medical graduate is in the pursuit merely of a modest livelihood, that he is possessed of the suitable character and ability, the requisite energy, perserverance, and, above all, love for his profession, to enable him to bear the brunts and buffets of its early disappointments and misfortunes; and that he is poor, but ambitious of honor and the prizes which are to be worn only amid "the madding crowd's ignoble strife"; what available opening is there for him in a large city?

It must be confessed at the outset that the picture presents no very attractive features in the foreground, although the distance hidden from view conceals, for all we know, the poet's land of Eldorado, and some who seek may find it. But to speak unmetaphorically, there is one line of work which may offer a possible opening to the young medical graduate, or to some of them at least, and as such I would draw favorable attention to it. I do this, moreover, with the greater confidence, because of my own experience, and because it is a line of work which is as yet comparatively new, and therefore not quite so overstocked as many other branches of medicine, and last but not least, on account of its emoluments, which though small are reasonably sure: I mean the municipal health department system and the study of sanitary science.

What is the health department system, and what are its status and its duties? These questions are often asked and imperfectly answered, and hence a false idea is apt to be conceived of the true nature of the work with which Health Departments have to deal.

The modern health department system as it now exists in our large cities—there is no National health department in this country, although many States have their departments of health—is a centralized, autocratic organization under municipal control, designed for the care of the public health. The word *autocratic*, and the acts which it involves, would be inimical, seemingly, to our principles as citizens of a democracy. Nevertheless in this Republic of ours the growing tendency of the times is evidently toward centralization and combination of wealth and power. Witness, not only the health department system, but the many other systems and syndicates, the giant trusts and monopolies in trade, political bossism, etc. A few of us may declaim against this tendency as denoting an infringement of the rights of the individual, a restriction of personal freedom, a destruction of competition, and so on; but, however, this may be in the main, the concentration of authority when it is plainly designed for the common good, as in matters pertaining to the public health, is not only accepted but welcomed by the people, despite its exercise of arbitrary power, on account of its certainly beneficient results, and this—as Dr. Biggs suggests in his Address on Public Medicine, delivered at the Sixty-fifth Annual Meeting of the British Medical Association—simply because our Government is democratic. *Pro bono publico.*

In like manner, not only here but everywhere, all broad-minded men, legislators and statesmen who have their country's welfare

and progress at heart, favor and encourage the public health department system. To quote the memorable words of Disraeli, England's great prime-minister, during a discussion in the British Parliament of a bill for the protection of the public health: "The public health is the foundation on which repose the happiness of the people and the power of a country. The care of the public health is the first duty of a statesman."

Nor are physicians on the whole really opposed to the health department system, although some may consider it to be against their interests to promote an organization which aims to prevent disease. Dr. Oliver Wendell Holmes once humorously remarked that "Physicians naturally desire for their patients great longevity with frequent illness"; and it has been said that "no medical practitioners, whose livelihood depends upon sickness, are likely to exert themselves in exterminating it." But the history of sanitary science, which is indissolubly connected with that of medicine, clearly shows this expression of opinion to be a libel on the profession; for the greatest achievements of hygiene or preventive medicine are the result almost entirely of the work, investigations and discoveries of medical men, and no class or profession has done so much for the preservation and prolongation of human life as the medical profession.

Let us look for a moment at the scope and character of the work, as shown by the functions performed by sanitary authorities. In its broadest interpretation, everything which is detrimental to health or dangerous to life may appropriately be regarded as coming within their province; and even those things which improperly or unnecessarily interfere with the comfort and enjoyment of life may also be rightly said to be the subject of their consideration and action. The duties of sanitary authorities, therefore, are far-reaching and complex in their nature. Primarily, they must insure to the community and to each individual an abundant supply of pure air, light and water, and wholesome food. The preservation of the purity of the air and the furnishing of an abundance of light and ventilation, involves comprehensive measures relating to the character of the habitations, their construction, their cleanliness and the cleanliness of their surroundings; the provision of efficient plumbing; good sewerage; sufficient air-space, and the prevention of overcrowding; protection against noxious vapors or odors arising from offensive trades, slaughter-houses, gas-works, decomposing animal and vegetable matter, and the purity of the atmosphere from suspended solid particles. It is also incumbent upon the sanitary authorities to prevent adulteration and to guarantee the wholesomeness of food—meat, milk, fish, fruit, and general articles of consumption. The purity and quality of various drinks must be inquired into, and the relative food values of different products determined. Beside special inspections relating to plumbing, ventilation, overcrowding, inspections of food, etc., there are also general inspections relating to street excavations, wells, privies, stables, the conditions surrounding the removal of garbage and dead animals, the conditions in public places and places of assembly, the manner and place of burial, etc. Another special feature of the work relates to the restriction and prevention of the infectious diseases, the inspection of reported cases, and the quarantine of patients affected with contagious affections and their removal to hospital when required; and the disinfection of infected premises, clothing, etc.

It is evident, from this brief survey of the functions of sanitary authorities, not only that the scope of the work is broad, but that the knowledge requisite for the discharge of the duties of medical health officer is comprehensive and for the most part totally unlike that required for medical practitioners. How is this knowledge to be acquired? Unfortunately there are as yet no schools in this country for the education and training of men in matters pertaining to public health. In consequence of this want, the necessary knowledge can only be obtained at present by actual service under the municipal health department system of one of our large cities.

As an illustration of this system, how it is organized, how appointments are made, what salaries are paid, and what advantages may be gained through the position of medical health officer, it may be interesting and instructive to describe shortly the organization of the New York City Department of Health, which may serve as a type of the best municipal health department systems in the United States.

The Board of Health of New York City (the Greater City of New York since 1898) is now composed of five members, namely, the President, who is the chief executive officer; two Commissioners of Health, who must be physicians (these three being appointed by the Mayor of the City), and two *ex-officio* members—the Health Officer of the Port of New York (who is a State officer nominated by the Governor) and the Police Commissioner of New York City (the latter being added to bring the Police Department and the Department of Health in closer relation to one another). The Board of Health has jurisdiction over the entire city of Greater New York, as it at present exists, with a population of over three and one-quarter million inhabitants. All of the administrative and executive work of the Department is concentrated at its main offices at 969 Sixth Avenue, and is carried on under the immediate direction of the chiefs of the various divisions into which the Department is divided.

The Sanitary Bureau is under the charge of the Sanitary Superintendent, who, as its chief

executive officer, has to do with the general supervision of the sanitary work of the Department, the enforcement of the provisions of the several sections of the Sanitary Code, and the laws and ordinances relating to tenement and lodging-houses, and generally the laws relating to the health of the city. This Bureau is subdivided as follows:

First Division, general and special sanitary inspection.

Second Division, contagious diseases and medical sanitary inspection.

Third Division, food inspection, offensive trades, etc.

Fourth Division, pathology and bacteriology.

Fifth Division, medical school inspection.

Sixth Division, marine inspection.

The Bureau of Records is in charge of the Registrar of Records and is entrusted with the registration of births, marriages, and deaths, the granting of burial permits, the study of topographical causes of disease and circumstances of unusual deaths, and, incidentally, the classification and filling of vital statistics.

There are also four hospitals under the control of the Board of Health, namely, the Willard Parker Hospital, the Reception Hospital, the Riverside Hospital (North Brother Island), and the Kingston Avenue Hospital (Brooklyn), which are devoted to the reception and care of those suffering from contagious diseases.

Each of the Boroughs of New York, Brooklyn, Queens, and Richmond, has its special health officers who act as deputies or assistants of the respective chiefs of the divisions, and each of the divisions and subdivisions of the Health Department has also its special employees, inspectors, etc., amounting in all (including hospital employees) to nearly eight hundred persons. Of these over three hundred are physicians. The medical corps, in which we are principally interested here, include the district medical inspectors, the district and special vaccinators, the inspectors for the administration of antitoxin, the diagnosticians, the bacteriologists, the medical school inspectors, and several special inspectors of disinfection of lodging-houses and public institutions. These various corps, with the exception of the summer corps and the school inspectors, are permanent and are on duty throughout the year. The medical school inspectors are on duty through the school year, and the work of the summer corps is limited to July and August.

Appointments to the New York City Department of Health being governed by the Civil Service rules, none of the positions above mentioned is obtainable except by competitive examination on the various subjects to which the work relates. Whenever the list of eligible candidates runs out, or in the judgment of the Board additional help is needed in the Department, a notice is published in the City Record, the official municipal organ, to the effect that a competitive examination will be held at the appointed time, to fill the vacancy or office advertised. Candidates for examination are then expected to make regular application through the Director of Civil Service, from whom blanks may be obtained for the purpose, and upon which are to be stated personal history, qualifications, etc., of the applicant, vouched for by at least three well-known citizens of New York, one or more of whom should be physicians in good standing. The examinations are strictly competitive, that is to say, only those who gain the required percentage of marks and pass at the head of the lists are eligible for appointment in the order of their proficiency. At one time, I believe, the Board of Health as the appointing power reserved the right to select from a certain number of those who on examination stood highest on the lists the ones whom they considered most fitted to fill the office; but I am unable to say whether this is still done. So far as I know, exception to the rule is now made only in favor of veterans of the army or navy, who, when otherwise eligible, have the preference of appointment.

The salaries paid to medical health officers, not including the chiefs of divisions, vary in amount from $1,800 to $900 per annum, the average being about $1,200 a year. The medical school inspectors receive $30 a month during the school term, and the summer corps of inspectors are paid $100 a month for two or three months at midsummer. Regularly on the first day of the month, and as long as the duties required are properly and punctually performed, every official of the Health Department receives a check for the amount of salary due, upon signature of his or her name on the pay-roll.

With regard to the character of the work required of medical health officers, it undoubtedly necessitates expert knowledge, which, in this country at least, cannot be acquired outside of the service of one of our large municipal health department systems. But with ordinary exercise of energy and assiduity in its daily performance, it is not difficult to gain the requisite knowledge in such a well organized system as that of the New York City Department of Health.

The time which each medical officer is expected to give to the work varies, of course, with its character and the orders of his chief of division; but every one must report for duty daily except Sundays and holidays, and there is a vacation of two weeks in the year. Certain officers, like the diagnosticians and bacteriologists, are assigned for special duty, alternately, on Sundays and holidays; and two diagnosticians are on duty in the main offices of the Department day and night. No absences are allowed without special permis-

sion of the Board through the chiefs of divisions, and in case of sickness a report must be sent at once to headquarters, a doctor's certificate being furnished later.

Inasmuch as the remuneration received for the work of the medical health officer is inadequate to secure the services of the highest class of physicians and expect them to devote all their time and labor to the Department, these officers are granted the privilege of carrying on a private practice in the city, or engaging in other professional occupation, in so far as this does not interfere with their duties as health department officials. There are, moreover, certain other compensatory advantages to be gained in connection with special kinds of work, and more particularly that of bacteriology, which affords a fruitful field for experience and investigation to those who are employed as bacteriologists and pathologists in the Health Department.

Until bacteriology shed the light of its discoveries on the origin and nature of infectious diseases, public hygiene or preventive medicine was but an incomplete science, and sanitary authorities were often compelled to blunder aimlessly in the dark. It was a new and important departure, therefore, from the old methods of Health Department work which was instituted in New York City (1892) at the suggestion and under the direction of Dr. Hermann M. Biggs, pathologist and director of the Bacteriological Laboratories, and for which he deserves the highest possible credit, namely, the establishment of a Bacteriological Laboratory as part of the Municipal Health Department system, this being the first laboratory of the kind ever established anywhere under municipal control. It was originally designed to afford facilities for the bacteriological diagnosis of Asiatic cholera, then threatening to invade the city, and for the investigation of questions relating to disinfection and disinfectants. A very short time, however, after the opening of the laboratory, the scope of the work was extended and facilities for the free bacteriological diagnosis of diphtheria were offered to the physicians of New York. The work in diphtheria was soon followed by the perfecting of arrangements for the free bacteriological examination of sputum for the diagnosis of cases of suspected tuberculosis among residents of the city. Then in 1894 investigations in connection with the production of diphtheria antitoxin were begun, and the municipal authorities having made a special annual appropriation (antitoxin fund) for the prosecution of this work, the Health Department undertook the manufacture of antitoxin in its own laboratories. The use of this product was commenced in 1895.

A portion of the diphtheria antitoxin was freely supplied to all public institutions in the city; antitoxin was also furnished free to physicians for use among persons too poor to pay for the remedy; and antitoxin was administered free on the request of the attending physician to any resident of New York City by a specially detailed staff of medical inspectors. The surplus antitoxin remaining after the public was supplied in this way was then sold, as authorized by a special act of legislature, "the proceeds to be devoted to the manufacture of diphtheria antitoxin and other antitoxins." The special fund thus accumulated made possible the establishment and maintenance of a "Hospital and Research Laboratory," devoted to the production, not only of diphtheria antitoxin, but of other bacteriological products, and to general experimental investigations in relation to the infectious diseases.

The work of this laboratory now includes the production of tetanus antitoxin, antistreptococcus serum, mallein and tuberculin (used by the Department in the diagnosis of glanders and tuberculosis, respectively, in animals), and numerous experimental researches regarding diphtheria, pneumonia, typhoid fever, tuberculosis, influenza, smallpox, etc. The administration of Pasteur's treatment for the prevention of rabies is also now being given at the Hospital and Research Laboratory free of charge to residents of New York City. There is a special laboratory and stable devoted to the manufacture of bovine vaccine virus, investigations undertaken in this laboratory having resulted in the production of glycerinated vaccine pulp of great activity and durability. Moreover a new laboratory is at present in course of construction for the special investigation of the bubonic plague. These laboratories are situated at the foot of East Sixteenth Street near the Willard Parker Hospital.

The routine bacteriological work is carried on in the "Diagnosis Laboratory" in the main office building of the Health Department (966 Sixth Avenue); and this work also includes, besides the examination of cultures and of sputum, respectively, in cases of suspected diphtheria and tuberculosis, the examination of blood and serum by the Widal test in cases of suspected typhoid fever. These routine examinations for diagnosis now amount to very many thousands in number in the course of the year. They serve the double purpose of assisting physicians in the city to arrive at positive conclusions in their clinical diagnoses, and of determining the action of the public health authorities with regard to the quarantine and disinfection of certain diseases.

Furthermore, it may be said, that the conspicuous reduction in the mortality of such wide-spread and fatal scourges as diphtheria and tuberculosis (the former of which has been reduced to about one-half of what it previously was) in New York City, has been largely due to the work done in the Bacteriological Laboratories.

It will be seen, from the foregoing description of the organization and work of the New

York City Department of Health, that the municipal health department system, as here exemplified, offers a wide and profitable field for cultivation, not only in all matters pertaining to public health, but more especially in certain lines of expert knowledge and scientific investigation. This system, however, of which New York may rightly be regarded as the pioneer and model, is not confined to this city; on the contrary, it now finds its analogues in many other cities of this and other countries, although there are perhaps few, if any, bacteriological laboratories anywhere so thoroughly equipped for Health Department work as those of New York City.

But so far we have spoken only of the possible advantages to be gained in the service of the Municipal Health Department system. Are there no disadvantages connected with it? Yes, there are, both in the position itself of medical health officer, and in the difficulty of getting the appointment; and to some these drawbacks and difficulties may appear to render the attempt to obtain or occupy a place as medical health officer as prohibitory, if not suicidal.

In the first place a medical officer of health is liable to become, although not necessarily so, and unpopular personage, to prevent which it may require on his part the exhibition of great tact and discrimination, not to speak of equanimity, in the discharge of his duties. This does not refer so much to the public in general, who at the worst may regard him perhaps as one degree removed above a police officer, as to his colleagues in the profession, some of whom will look upon him possibly as a usurper and dictator in medical matters, about which he cannot, in their opinion, know as much as they do, as experienced practitioners. This fact, together with the time he is expected to give to the Department, although he has several hours a day to devote to his own affairs may tend to detract from rather than to add to, his chances of success in private practice. Nor, for the same reason, does his connection with the Health Department bring him any positive advancement in the social scale of life. Then, too, as a matter of course, no man who is a public servant can expect to be his own master entirely, especially if he hold only a subordinate position. He is under orders of his superior officer and must conform to certain rules of discipline, being required not only to perform his routine work properly and punctually, but to be ready at a moment's notice and on any emergency by day or night, to drop all private business, however urgent or important, to obey duty's call whenever or wherever that may be.

Moreover, despite these apparent disadvantages, the position of health officer is not at all easy to obtain. For having a fixed salary attached to it—a rarity in medicine, even it if be only a paltry $100 a month—there are many who covet it. For every vacancy or additional place to be filled there are often a hundred or more applicants; and few of these vacancies and places occur. No one under the Civil Service rules can be discharged except for neglect of duty, hence dismissals are rare. This is not only because those in office are very circumspect in their work and conduct, not to give cause for dismissal, but also because the character of the work is such that it necessitates the retention in office as long as possible of men who have been specially trained for its performance. And it is manifest that no body ever resigns voluntarily a paid position unless he has something better in view, or at least the insurance of a similar income in the receipt of which he will enjoy greater independence and superior advantages.

But for all that, the situation is not quite as black as it is here painted. Nor do I wish, in concluding my paper on the health department system, to leave behind a pessimistic impression of its work and influence. Far from it; for although I do not desire to pose as special pleader or spokesman for any health department in particular, I am a staunch supporter and advocate of the system in general. The minor disadvantages connected with the position will depend to a large extent upon one's own personal character and behavior, and they are, in my judgment, more than counter-balanced by the possible advantages to be gained as medical health officer. The obstacles in the way of appointment are undoubtedly great, but not insuperable, as is evident from the fact that these positions have been, and are being, constantly secured by others.

Finally, with regard to the work itself, I believe that there is nothing which a young medical graduate can undertake at the present time that will give him a broader field of vision in his profession especially at the beginning of his career, or more opportunity to do "the greatest good to the greatest number," while certainly benefiting himself, than the study of sanitary science and preventive medicine under the modern municipal health department system.

THE ADVANTAGES IN EXAMINING FOR LIFE INSURANCE.

BY BRANDRETH SYMONDS, A.M., M.D.,

OF NEW YORK;

ASSISTANT MEDICAL DIRECTOR OF THE MUTUAL LIFE INSURANCE COMPANY OF NEW YORK.

At the request of the Editor, I wish to set forth some of the advantages which accrue to the active practitioner when he becomes a medical examiner for life insurance. I can only speak in this connection for a legal-reserve, level-premium company, for my experience has been confined exclusively to that field. I know nothing of the practical workings of industrial and assessment insurance.

What I have to say must, therefore, be considered entirely foreign to those forms of insurance and applicable only to those companies which are sometimes called "old line companies." These all require about the same standard in their examiners and most of them pay the same fees, so that observations suitable for one are generally appropriate to all.

The standard set by the companies is a high one and the fee paid is large enough to warrant the best of workmanship. A medical examiner must be not only a good physical diagnostician, but also a man of tact and discretion. Above all he must have a firm backbone and a resolute aversion to being cajoled even by the most plausible agent. It is not always a easy matter to avoid this but it is a prime requisite. He must also be careful and precise in recording the answers to the various questions. To study the examination in black and white is quite a different matter from examining the applicant in flesh and blood. A small omission in an answer may entail considerable correspondence and much delay, which may prove fatal to the agent's hopes. The examiner must be prompt in keeping his appointments. It is true these cases are not matters of life and death, but they mean bread and butter to the agent. It is not right to disappoint him, as he may have worked long and hard on a case. Failure to keep appointments is the most common cause of dissatisfaction on the part of an agent. He generally rectifies it after a few mishaps by ceasing to use that examiner, and then the examiner feels that he has a grievance.

It may be observed that these remarks so far apply to the qualifications of the examiner and not to the rewards which he is supposed to get. That is true, but we also show that the best man deserves the prize. The successful general practitioner is the one who possesses the qualities needed to make a successful life insurance examiner. He is the one that the company wants. Especially in his earlier years he will find the rewards of great advantage. Long before his practice has grown so large that he is known to everybody, he will find that his interest in life insurance work begins to diminish, for the encroachments of clinical practice will begin to hamper him. When he finds that he can no longer give the time and attention which it deserves, let him say so to the company. Do not let him be a dog in the manger, who cannot do the work himself and begrudges anybody else having a share in it. He can often make it his privilege to pick out his successor, thereby still retaining some influence. His position, though shorn of some prizes, will preserve its connection with the company and the latter is very glad to avail itself of his advice and counsel, when he can give it.

The rewards due a medical examiner for a life insurance company can be divided under several heads.

1. Let us consider the pecuniary aspects, as this naturally occurs first to most people. The fee that nearly all first-class companies pay for each examination is $5.00. This includes the answering of a number of questions, a thorough physical examination of the applicant and a chemical examination of the urine. It does not include a microscopical examination of the urine, as this is required only under special conditions and then an extra fee is paid for it. The same fee is paid whether the case is accepted or declined, so that no premium is put upon the wishes of an agent to have a case passed.

This is good pay for the work required, as good as any doctor gets except a few high-priced consulting specialists in the large cities. I do not know of any place where the regular fee for the first visit is over $5.00, and this visit should include the careful anamnesis, a thorough physical examination, a chemical examination at least of the urine, and a scheme of therapeutic procedure which contains a prescription or two, an outline of dietary and many other details. There is usually also a more or less guarded prognosis and some talk, perhaps discussion, with other members of the family. All this service is rendered in the great majority of cases for a fee no larger than $2.00 or $3.00, and the average doctor as he rides away wonders whether he will be able to collect a cent, and when. Now, with a life insurance company his collections are 100 per cent. good, payable each month, and the work certainly is easier and takes less time. Occasionally the company requires him to see the applicant again, but that is due in most cases to the examiner's own carelessness in not fully or properly answering the questions which are plainly set forth in the examination blank. Outside of these mishaps, which are his own fault, the occasions on which a company calls for additional work within the prescribed fee are comparatively rare. It seems to me that the pecuniary reward alone should make every young practitioner eager to qualify as examiner to as many life insurance companies as he can.

2. From a professional standpoint, a medical examiner for a first-class insurance company may be considered as one who is endorsed and approved by competent authorities after careful investigation. A life insurance company takes great pains and goes to much expense to pick out the best men they can find in a place. It sifts the wheat from the chaff, and when it asks a physician to be a medical examiner it signifies thereby that he ranks among the first of his associates. The public understand this and value the recognition which a doctor thereby obtains. The profession appreciate it, too, although the unfortunate who does not

obtain these prizes may affect to sneer at them. But notice how eagerly he seizes any opportunity to prefer his claim for such a position. See how the experienced agent works on his gullibility by assuring him of an examinership if he will only take out a $10,000 policy, the premium on which he will easily be able to pay out of his fees, according to the plausible agent. This story is old and frequent, but to the pain of the profession be it said, it is perennially fresh to some credulous ones. In a well-regulated company it is a most certain way of not having one's desires gratified.

3. From a scientific point of view examining for life insurance also has its advantage. It enlarges one's sphere of observation and opens up a phase of human nature which has never been presented to him before. He has to rely to a much greater extent upon physical diagnosis, for in this new field he will find that patients minimize their symptoms. The most conscientious applicant will insensibly gloss over his previous mishaps, and a less scrupulous one will force the skill of the examiner to the utmost. How often do we find under careful cross-questioning that the simple chancroid cured in a few weeks develops into a typical case of syphilis; how a little blood-stained mucus grows into an ordinary pulmonary hemoptysis. This is not the pleasant side of human nature, but unfortunately it is very common, and a physician is all the better equipped for having seen some of it. It makes him more self-reliant, gives a greater dignity to his physical examinations, and teaches him the self-respect due his own keen observation.

4. It is also a social advantage outside of the recognition which it obtains for him in the profession. The public appreciates the position which he holds and respects the confidence shown in him by the company. He meets life insurance agents of all degrees and shade and acquires a great deal of tact in treating their requests and desires, many of which he is unable to comply with. An agent works hard to interest an applicant, he is human, and he discounts the future as thoroughly as the average man. When he gets an application signed he feels that the commission is in his pocket, and not infrequently he spends it. Naturally a rejection is a great disappointment and he is very apt to take it hard. A medical examiner learns to handle him with such tact under these circumstances that no friction is developed and at least an outward appearance of satisfaction is maintained. This experience is of use to the examiner in all his work, as it is no light accomplishment to convert a disgruntled man into a complaisant one without changing one's own views. It also develops a moral backbone, a very wholesome thing to have in all walks of life.

These are some of the advantages of examining for life insurance and they are appreciated by the best men in the profession. For instance, Dr. Henry M. Lyman, Dean of the Rush Medical School and Professor of Practice in the same, has been for years our chief medical examiner in Chicago. It is only during the past year that his health has prevented him from doing the major part of the work as heretofore. In New Orleans Dr. John B. Elliott, Sr., Professor of Practice in the Medical Department of Tulane University, holds the same position. I could mention many others of equal rank in the profession who are examiners for life insurance.

Of course there are some difficulties. The work is exacting and requires careful, conscientious attention, and therefore a lazy or careless man will find it hard. It also calls for a high grade of medical knowledge and, therefore, the ignorant or badly-educated man will find it impossible. It demands the strictest integrity and therefore the corruptible man will find no place for himself. But to the honest, bright, up-to-date practitioner examining for life insurance offers great inducements. He may even become so absorbed in this class of work that he seriously neglects his other professional duties and is tempted to give them up entirely that he may have more time to devote to this specialty. This is a great mistake and must be carefully guarded against. A good examiner must keep himself constantly informed of the progress of medical science and he should be constantly in touch with the practice of his profession. A physician should never give up his practice simply in order to make examinations for life insurance.

THE OUTLOOK FOR THE YOUNG PHYSICIAN IN STATE HOSPITAL AND SANITARIUM WORK.

BY CARLOS F. MACDONALD, A.M., M.D.,

OF NEW YORK;

PROFESSOR OF MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; EX-PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY.

It is assumed that every young physician on receiving the degree which admits him to the dignity of the doctorate in medicine is desirous of qualifying himself to meet the highest demands of professional life through the attainment of a thorough training and experience in a general hospital, which training and experience are nowadays regarded as essential to the completion of a preliminary medical education, even though a hospital course is not obligatory. In other words, a medical degree while it confers the legal right to practise medicine does not in itself afford a man professional standing nor imply the moral right to practise which a proper training alone can give.

Probably the most important question which confronts the recent graduate in medicine, as he

is about to enter upon the threshold of his professional career is how to start in practice. In common with other medical teachers, I have frequently been asked by the student or young physician, as to what branch or department of medicine I would advise him to take up. To this I have usually replied: "Take up that branch for which you find you have an aptitude and liking after you have had sufficient experience in general medicine to enable you to form an intelligent judgment in respect to the question." The young physician is prone to feel that certain departments of medicine are distasteful to him, or at least not to his liking, and to think that by ignoring these and devoting his energies to the particular branch in which he feels most interest he will more speedily become proficient in that. This process of reasoning is too often misleading and, if acted upon, will almost certainly result disastrously. The constantly widening scope of medical science renders it difficult, if not impossible, for one man to become skilled in every department thereof, hence the tendency to a division of professional labor into specialties which has come to pass. The true specialist, however, is not a "hot house" growth, so to speak, but, instead, is a natural outgrowth in the broad field of general medicine in which he had become well grounded before developing the qualities of an expert through the discovery of a special aptitude or taste which has led him by a process of evolution, as it were, into the particular field of practice in which he finally acquires an especial reputation. The specialist whose superstructure of knowledge rests upon a broad and deep foundation of varied experience in general medicine is not likely to dwarf the measure of his professional capacity by the habit of overestimating the importance of his specialty and thus lose sight of other influences which may have an important bearing upon the disease for which his special knowledge and skill are sought. On the contrary, his experience in general medicine has rendered him sufficiently familiar with the phenomena of disease to enable him to exercise a sound judgment in the practice of his specialty.

This brings me to the subject of which I desire to speak, in compliance with a request of the Editor of the Medical News, namely, "What are the chances of the young physician in State hospital and sanitarium work; that is, in institutions for the insane, whether public or private?"

First, as to the State hospitals, it may be said that the medical service in State hospitals for the insane, especially in the State of New York, offers to the young physician a most inviting field for the clinical study of mental disease as well as in the matter of pecuniary compensation and allowances, which, in comparison with the pay and allowances of medical officers in other eleemosynary institutions, are on a very liberal scale. Then, too, a position on the medical staff of a State hospital is one of honor, dignity and responsibility, as well as a credential to the best society in the community in which the hospital is situated, if the incumbent chooses to make it so. The medical service in the New York State hospitals for the insane is graded as regards rank and pay respectively as follows: medical superintendents, $3,500 to $4,500 per annum, and maintenance for self and family; first assistant physicians, $2,000 to $2,500 per annum, and maintenance for self and family; second assistant physicians, $1,500 to $2,000 per annum and maintenance for self; assistant physicians, $1,200 to $1,500 per annum and maintenance; junior assistant physicians, $900 to $1,200 per annum and maintenance. The number of physicians inclusive of superintendents and medical internes is about 130. The number of medical officers allowed for each hospital is as follows: one medical superintendent, who is appointed by the managers and who is the chief executive officer of the hospital and has the general superintendence of the entire hospital plant, together with its furniture, fixtures and stock and the direction and control of all persons therein; one first assistant physician, who is the superintendent's deputy and who acts in the capacity of superintendent in case of absence or illness of the latter; a second assistant physician, who usually has charge of a department of the hospital or of a group of buildings, where there are detached buildings; assistant physicians, usually one in charge of each department, assisted by a junior physician. The number of assistant and junior physicians in each hospital is determined by the State Commission in Lunacy in accordance with the number of patients, the ratio being one staff physician to about two hundred patients. Each State hospital is also required by law to have one woman physician on its staff, at an annual salary of $1,000 to $1,500 and maintenance, but who is not in the line of promotion. All medical officers receive an increase of salary from the minimum to the maximum of their respective grades at the rate of $100 for each year of continuous service. Superintendents are appointed by the Board of Managers and all other medical officers by the superintendent. Appointments are made only from certified lists furnished by the State Civil Service Commission before whom the candidate must have passed a competitive civil service examination. Certain qualifications are requisite in order to become eligible for this examination, namely, for the position of superintendent candidates must be well-educated physicians, graduates of an incorporated medical college and have had at least five years actual experience in an institution for the insane; candidates for first assistant must possess qualifications like those prescribed for superintendents except that the period of experience in an institution for the insane is reduced to three years. Physicians below the grade of superintendent and first assistant, other than women physicians, must enter the service as

juniors. Candidates for examination for the position of junior must be legally qualified practitioners of medicine.

Under existing regulations promotions of assistant physicians to the grade of second assistant, also of juniors to the grade of assistant physician, may be made upon the ground of fitness and merit irrespective of length of service and without further civil service examination. This regulation is designed to furnish an incentive to officers in these grades to merit promotion. Application blanks and information as to time and place of holding examinations for positions of assistant physician and junior physicians may be obtained from the Secretary of the State Civil Service Commission, Albany, N. Y. The names of successful candidates are placed on the "eligible list," in the office of the Commission, from which selections are made whenever vacancies occur. In view of the fact that these examinations are usually a bugbear to young physicians it should be said that the questions—about twenty in all—relate only to medicine, surgery, obstetrics, physiology, etc., and are of such a nature that any recent graduate should be able to answer them readily. The examinations are in writing and candidates are allowed five hours in which to complete them.

In addition to the regular medical staff each hospital is allowed two medical internes or clinical assistants who receive an annual salary of $600 and maintenance. These positions are open to recent graduates in medicine and serve as a stepping-stone to staff appointments, especially to civil service "eligibles" while awaiting a vacancy on the regular staff. Internes are appointed by the superintendents, after a formal civil service examination held at the hospital by a local examining board. The medical service of the New York State hospitals is practically free from partisan influences, the tenure of office being secure during good behavior and efficient service. Each officer is allowed an annual vacation with full pay during absence. Thus it will be seen that the attainment of a superintendency is open to every medical officer in the service who proves himself efficient and worthy. It is safe to say that among the present superintendents of the New York State hospitals—17 in all—there is not one who did not reach his position within a period of ten years from the time he entered the service. Here, as in other fields of labor, promotion invariably comes without seeking to him who proves his fitness therefor by a faithful, efficient and zealous performance of the duties which fall to his lot. In fact, it is merely a question of the survival of the fittest, a race in which the drones and laggards are left behind.

In addition to salaries, the allowances which the State makes to medical officers of hospitals for the insane are most liberal. The living apartments of superintendents and their families—in some instances separate houses being provided— are in all cases ample and in some even palatial in point of construction and arrangement, as well as luxuriously furnished. Servants, cooks, waitresses, chambermaids, coachmen, etc., are supplied by the State; also horses and carriages, unlimited laundry facilities, and, in fact, everything that is essential to a gentleman's well ordered home. In addition to these, superintendents have the free use of telegraph, telephone, stationery, stenographers, etc., also liberal table supplies and, incidentally, the use of the products of the farm, garden, green houses, etc. It is estimated that these allowances, exclusive of salary, are equivalent in value to $10,000 or $12,000 per annum. The hospitals are also liberally supplied by the State with standard medical books and journals, instruments of precision and in fact everything in the way of medical and surgical appliances, laboratory facilities and equipments, etc., that belong to a well organized modern hospital for the insane. Add to these the wealth of clinical and pathological material with which the hospitals abound and it at once becomes apparent that the statement which I made at the outset, that "the medical service in State hospitals for the insane offers to the young physician a most inviting field," is not an exaggerated one. Moreover, the opportunity of making a reputation as an alienist that will insure success in the private and forensic practice of mental medicine is open to every medical officer who chooses to avail himself of it. To this end "the good assistant physician" will cultivate a true scientific spirit and professional zeal by a careful and systematic study of the numerous interesting cases in his service, writing them up from time to time for presentation to medical societies and to medical journals. These are the way in which medical men make legitimate and lasting reputations. The bane of State hospital life and one which the far-sighted and ambitious staff physician will studiously avoid, is a tendency to routinism and perfunctory performance of duty. The men who yield to this tendency, and I regret to say that many do, rarely attain to a superintendency or to high repute as specialists.

Respecting the chances of the young physician in private institutions or so-called sanitariums for the insane, the subject may be disposed of in few words. There are two classes of private establishments for the insane, namely, incorporated private asylums, or hospitals, and small sanitaria that are conducted on the so-called "family plan." The former are comparatively large, quasi public institutions under the control of boards of managers or governors and are organized and equipped much like the State hospital, having a medical superintendent and staff of assistant physicians. The latter are appointed by the superintendent and are not subject to civil service requirements. These institutions receive only private or "pay" patients, and, while the clini-

cal advantages to be had therein are nearly if not quite as great as those in the State hospitals, the pay and allowances are generally less, as also are the chances of promotion; nevertheless, the medical service in this class of institutions offers many attractions to the young physician in the way of clinical advantages and comfortable surroundings.

It need hardly be said that owing to the comparatively small numbers and the class—wealthy—of patients treated therein, the small private sanitaria for the insane afford only meager opportunity for the clinical study of mental diseases and practically none at all for pathologic investigation. All of the legitimate institutions of this class in the State of New York are licensed by the State Commission in Lunacy and are subject to visitation by that body. The medical head of the institution who usually is also the proprietor or owner, is designated officially by the Commission "Physician in Charge," and he must have had five years actual experience in the care and treatment of the insane in order to obtain a license. Assistant physicians are appointed by the physician in charge, subject only to formal approval by the Commission as to good character and the legal right to practise medicine. The rate of compensation is determined by mutual agreement between employer and employed. Most of the proprietors of strictly private institutions for the insane throughout the country are men who have acquired a practical knowledge of the treatment and care of the insane in public institutions for that class, a fact which suggests another inducement for young physicians to become proficient in "ministering to a mind diseased."

The number of physicians engaged in private asylum work in the State of New York is about 40.

In conclusion, there are a large number of hospitals and institutions for the insane throughout the United States in which numerous physicians find useful, profitable and congenial professional occupation.

85 Madison Avenue.

THE MEDICAL MAN IN THE UNITED STATES MARINE-HOSPITAL SERVICE.

Not every man who passes brilliant examinations, nor every keen, eager worker in a medical school is sure of success in the practice of medicine. So many elements enter into the qualifications of a physician who works up a large practice that the medical education is but the foundation of success, and not the means to it. Sufficient capital to furnish and equip an office, sufficient means to move in good society until the practice comes; good breeding, tact and some social accomplishment to make one attractive as a man; without some one of these, the man of brains finds it difficult to bridge over these years between the time when he first signs his name as a physician, and the day when he has made it known.

It is therefore a sign of wisdom when the graduate pauses to ask himself whether the mental qualities that brought him honors in his medical course are supplemented by those social and material attributes that will bring him a good practice. If he be a man of parts, and more keenly interested in his work than in the business side of it, he may find the best expression of his powers in the Marine-Hospital Service. The Treasury Department of the United States Government offers to the ablest youths of the country an assured income and excellent social position, and what is practically an appointment for life to those that are best qualified to fill the positions.

It is by no means the desire to paint the life of the Marine-Hospital Service in alluring colors in order to induce young men to enter the examinations, as this is entirely unnecessary, for the classes at present are as large as can well be handled, and the tendency is towards increasing members, but as the time for passing the examinations is limited to the ages from twenty-one to thirty, it is well for those who think of entering this branch of the profession to take their examinations as soon after their graduation and hospital service as is possible, for the qualifying examinations are very severe and exhaustive. It is not that the actual book knowledge required is any more than that required by any first-class college, but the knowledge in every branch must be extremely thorough and practical, so much so that unless a man takes a special course of training for a few months it is difficult for him to attain the 80 per cent. that places him on the eligible list.

The positions, however, are well worth the effort of special preparation, for these detailed and comprehensive examinations. They insure good incomes which increase every five years irrespective of promotion. If a medical officer incurs a permanent disability he is retired on a comfortable pension.

The assured position is apt to tempt men who feel that the world owes them a living to consider the Service as something to fall back upon; but it is by no means an asylum for the not-over-energetic nor a pensioned shelter for the broken-down; it is a very exacting and comprehensive service on which the health of the country at large depends. The physical examination, in the first place, throws out all but men of robust physique, for as they must live in any part of the country that the Government chooses to place them, they must be able to stand any climate and also great strain of work in times of emergency. The preliminary requisites of education are high, and the moral tone of the candidates is carefully considered; so that in order to compete at all for the position a man must be above the average, and even after he has passed his examinations satisfactorily he is merely eligible for appointment, and if no appointment comes to

him within a year he must be re-examined. The examining board hold for themselves the privilege at any time to decline to continue a man's examinations, if for any reason they feel sure that he would not make a suitable candidate, and no amount of influence, or wire-pulling or politics can get a man into one of these life positions if his own personal merits do not commend him to the examiners.

The general information regarding the examinations may be briefly summed up as follows: Examinations are usually held once a year, in the spring, sometimes more frequently. The boards meet either in Washington or New York. All applicants must be graduates of reputable medical colleges. They are given, first, a physical examination, including a test of color vision. Absolute health is a prerequisite to appointment. Each applicant then writes a personal history of himself, giving his educational advantages, etc. A written examination is then conducted in the chief branches of medicine, including anatomy, physiology, chemistry, materia medica and therapeutics, practice of medicine, practice of surgery, obstetrics and diseases of women, hygiene, pathology and bacteriology. This is followed by a brief clinical examination in a hospital. Added to this is an oral examination in common school branches, also the collateral sciences and literature, sufficient to demonstrate the scope of each applicant's preliminary education. Each applicant reaching the grade of 80 is eligible for one year and appointments are made to vacancies as they occur in the relative order of merit.

In addition to the Surgeon-General, the corps consists of three grades, namely, Surgeons, Passed Assistant Surgeons and Assistant Surgeons. A successful applicant is appointed to the grade of Assistant Surgeon and is usually first assigned to one of the large Marine Hospitals in order to become familiar with the routine work of the Service. His salary is $1,600 per annum. After five years' service as an Assistant Surgeon, the officer is eligible for examination for promotion to the grade of Passed Assistant Surgeon, with a salary of $2,000. Appointments to the grade of Surgeon are made in the order of seniority from the list of Passed Assistant Surgeons, as vacancies occur in the list of Surgeons. The salary of a Surgeon is $2,500.

United States Marine Hospitals are located on all the navigable waters of the United States. The chief stations on the Atlantic Coast are as follows: Portland, Me.; Boston and Vineyard Haven, Mass.; New York, N. Y.,; Philadelphia, Pa.; Baltimore, Md.; Norfolk, Va.; Wilmington, N. C.; Charleston, S. C.; and Savannah, Ga. Those on the Gulf Coast are at Key West, Fla.; Mobile, Ala.; New Orleans, La.; and Galveston, Tex. On the Pacific Coast, stations are located at Port Townsend, Wash.; Portland, Ore.; and San Francisco, and San Diego, Cal. On the Great Lakes, the chief ports are Detroit, Mich.; Chicago, Ill.! Cleveland, O.; and Buffalo, N. Y. On the Ohio and Mississippi Rivers, officers are stationed as follows: Pittsburg, Pa.; Cincinnati, O.; Louisville, Ky.; Evansville, Ind.; Cairo, Ill.; St. Louis, Mo.; and Memphis, Tenn.

In addition to the Marine Hospitals, there are twelve national quarantine stations controlled by the Marine-Hospital Service, which are located at various seaports on the Atlantic, Pacific and Gulf coasts of the United States.

The hospitals are furnished with good medical libraries and are also supplied with a number of medical journals. Each hospital is equipped with a working clinical laboratory, also photographic and other scientific apparatus.

The Service conducts in Washington one of the best-equipped laboratories in the world, and a bill is now in Congress providing for a separate building for same. It is the policy of the Service to detail young officers in small classes for a term of service in this laboratory with a view to equipping them as scientific clinicians and practical bacteriologists. Several officers who have shown special aptitude in this line of work have been educated by the Service in the best laboratories of Europe. Encouragement is given to those who desire to pursue surgery or special lines of investigation and officers are urged to join medical societies and mingle with members of the profession in order to increase their own knowledge and promote the efficiency of the Service. They are permitted to publish professional reports based upon their own observations in hospitals of the Service. The Service treats something over fifty thousand patients a year.

One duty of the medical officers is to examine arriving alien immigrants and, at times when epidemic disease threatens to invade the United States from Europe, officers are detailed to serve in the chief European seaports for the purpose of inspecting emigrants before embarkation. Occasionally an officer or a commission of officers is detailed to proceed to foreign ports for the purpose of making investigations along particular lines.

With the annexation of the new possessions and dependencies of the United States, the Marine-Hospital service has extended to such territory and officers are now stationed in Cuba, Porto Rico, Hawaii and the Philippines.

In times of epidemic disease in the United States when such disease threatens to invade one State or Territory from another State or Territory, the Marine-Hospital Service takes control and institutes measures for the suppression of the same.

Thus the particular abilities of the different officers of the Service are at the command of the country's particular needs, so that the energetic man with a power of organization or the expert bacteriologist, or the accomplished diplomat all have a chance to rise to prominent positions in the medical profession.

Monument to Dr. Skene.—A movement is on foot to erect a monument to Dr. Alexander Skene of Brooklyn.

MEDICAL PROGRESS.

Suprarenal for the Pain of Carcinoma.—When morphine, orthroform, nepthene, cocaine, and many other local and general analgesics fail to give relief from pain in advanced or recurrent carcinoma, E. A. Peters (*Lancet*, Mch. 2, 1901) cites cases in which suprarenal extract has proved invaluable. He uses a 10-per-cent. solution and applies it locally two or three times in twenty-four hours. One patient with malignant esophageal stricture, after weeks of pain found immediate relief from sipping one teaspoonful of the 10-per-cent. extract. It would seem to be most valuable in this class of cases.

Fetal Periods of Stress.—The neuron of the human being passes through stages corresponding to those found in the adult fish, frog, bird, and mammal. In fish and batrachia the cerebral hemispheres do not cover the region of the third ventricle from which the eyes arise; the same in the human embryo of seven weeks. In reptiles and birds the hemispheres cover this, but leave exposed the region of the optic lobes, as in the human of the middle of the third month. In mammals the hemispheres cover cerebellum, medulla and olfactory lobes as in the human embryo at fifth month. In some mammals even of high order (*e. g.*, Hapalidæ) the hemispheres are smooth as in fifth month of human embryo. At any time fetal stress may cause arrest of development of the neurons. The power of passing through the fetal period of stress will depend on the condition of the fetus at the time. J. G. Kiernan (*Medicine*, Apr., 1901) considers the most important of these periods to be the senile or simian (about four and one-half months) and that of sex differentiation. Arrest of development at the senile period may cause precocity and premature senility. If caused by syphilis there is the after-birth interference with the child's development. As to sex differentiation, long after impregnation nutrition is still influential, and even after the sexual organs have developed, poor maternal nutrition may arrest female development and cause reversion to the male type. At any time in life development may be arrested so that persons remain youthful. Such females are sexually anesthetic prostitutes, prurient prudes, hysteric reformers or gossip-mongers. Males may have the female instincts of modesty toward men and a liking for female occupations.

"Ureine" Non Est.—W. S. Haines and C. S. Woods (*Medicine*, Apr., 1901) have made extensive experiments in a search for the "ureine" described by Moor. They conclude that there is no such substance and that Moor's "ureine" is simply a strong aqueous solution of well-known urinary solids and of chemicals used in operating on the urine.

Atmospheric Ozone and Bacteria.—Some interesting experimental conclusions as to the bactericidal power of what they call "dry ozone" are detailed (*Lancet*, March 2, 1901) by Ransome and Foulerton. They tend to upset the time-honored view of the ozone of the pine forest. They are as follows: (1) Ozone in the dry state and under the conditions in which it occurs in Nature has no appreciable action on the vitality of pathogenic bacteria; (2) moist ozone is a very efficient bactericidal agent; (3) this suggests an interesting relation between dry ozone and water-free chlorine or sulphur dioxide; (4) so far as is now known any purifying action which ozone may have in Nature's economy is due to its oxidation of organic matter rather than to any direct bactericidal power. It interferes with bacterial growth only by the destruction of available food supply.

Temporary Uterine Fixation.—H. Rose (*Centralbl. f. Gynäk.*, 1901, No. 12) calls attention to an operative procedure calculated to prevent retro-uterine adhesions in such conditions as extra-uterine gestation. He calls it temporary ventro- or vaginofixation, because the supporting suture is absorbed before any permanent adhesions are formed and thus the normally free mobility of the organ is resumed. In ventrofixation he passes an ordinary heavy catgut suture through one horn of the uterus at the origin of the round ligament and ties the same in the usual manner in the abdominal parieties. Thus the uterus is hung up obliquely out of the pelvic cavity away from the peritoneum ripe for adhesions. Only a single point is in contact with the parietal peritoneum and any adhesions which may form at it are not enough to support the womb after the catgut is absorbed. In the vaginal fixation in colpoceliotomy anterior the catgut armed with two needles is passed through one or both round ligaments at their roots *extraperitoneally* and emerge through the vaginal substance, one on either side of the wound, while the bladder is strongly drawn upward by an assistant. The peritoneum is now sutured and the vaginal wound closed in the usual style. Then this supporting suture is drawn out until the uterus comes up out of the Douglas cul-de-sac and then tied. Its office is performed by the time the gut is absorbed.

Enteroptosis.—In a résumé upon this subject M. Einhorn (*Med. Rec.*, Apr. 13, 1901) follows the nomenclature of Glénard who applies the term to a prolapse of one or more abdominal viscera. The corset is undoubtedly a very important factor in the causation of these abnormalities. It is said that the total pressure of the corset varies between thirty and eighty pounds. The liver suffers from direct pressure, the other abdominal organs are pressed downward and the pelvic floor bulges by tight lacing about one-third of an inch. Constitutional weakness is also considered a predisposing cause. Enteroptosis is accompanied in most cases with movable kidney and occurs in about 33 per cent. of females having digestive troubles, and in about 6 per cent. of males having the same disturbances. No symp-

toms may be present. Usually, however, there is a faint feeling or weakness after arising. Sensation of fatigue with pronounced backache after walking is common in women, and a dragging sensation in epigastrium is frequent. Flatulence, and constipation are usually present and frequent micturition is found in a large number of cases. Physical examination shows usually a lax abdomen, organs easily palpated, and a depression in epigastrium with protrusion below when the patient stands. The position of the stomach can be demonstrated by splashing sounds, by insufflation with gas or water or by the use of a gastrodiaphone. An auxillary in diagnosis is Glénard's "belt test," in which the physician stands behind the patient encircling the abdomen with the hands and thus supporting the lower portion. Relief of distress speaks in favor of enteroptosis. The prognosis is good, but complete cures are naturally very rare. The principal part of the treatment of these cases consists in the application of a well-fitting abdominal supporter, ample nutrition and exercise. The bandage should be provided with windows over the iliac crests, also with straps at the thighs which prevent slipping up. Rose recommended the use of adhesive plaster over the lower part of abdomen. Overfeeding, if possible, outdoor exercise and intragastric electricity are especially indicated.

Intestinal Obstruction.—W. J. Walsham (*Brit. Med. Jour.*, March 23, 1901) in discussing intestinal obstruction calls especial attention to a cause usually overlooked by most authors. It is the reduction of an old hernia, usually by the patient, occasionally by the physician, *en masse*, that is, sac with contents and all complete through the canal of exit into the body cavity. If the hernia is already strangulated, of course, the process goes on to the surprise and discouragement of the attending doctor. If the hernia be simply incarcerated strangulation will sooner or later appear, depending upon the usual accidental circumstances. The history going with this condition is a very painful, rather forcible, at first slow, then very sudden reduction, beginning and continuing with the pain and ending with "a pop," but usually without cessation of the symptoms of strangulation. As a rule just within the ring of the canal a tumor can be palpated and percussed which represents the hernial mass. The treatment consists of laparotomy and whatever management its findings indicate.

Intussusception.—C. P. Clubbe (*Brit. Med. Jour.*, March 23, 1901) says that the diagnosis of this fatal and rather common condition in childhood must be made at the earliest possible moment and only can be reached by studious examination of the patient and careful history of the course of the disease has run. The treatment must be initiated without any delay. The first step must always be an enema, no matter at what stage of the condition the patient is first seen. Often an enema carefully given will reduce the invagination at least in part and convert one situated in the pelvis on the left, perhaps in the rectum itself, to one situated at the ileocecal juncture, where the trouble really began. Thus the operation itself will be much easier and briefer. For such an injection anesthesia to the surgical degree must be given always, to secure absolute relaxation of the patient, freedom from any pain, all possible decrease in the shock, and the possibility of observing the degree of the reduction. Should the injection fail to produce any improvement or total reduction a laparotomy must be at once undertaken. When the site of difficulty is reached, the invagination must be reduced by gentle squeezing on the *intussuscipiens*, never by traction on the *intussusceptum*. If success follows the effort the bowel must be examined because if dead a resection must be done at once. Such resection is the only rational treatment when other means fail. When the appendix has been involved in the invagination, on general principles it should be removed because its highly vulnerable organization makes it liable to necrosis although the rest of the bowel may recover.

Jacksonian Epilepsy, with Craniotomy and Implantation of Eggshell Membrane.—W. J. Greer (*Bristol. Med. Chir. Jour.*, March, 1901) reports in detail the case of a young woman, who eleven years ago sustained a fracture of the skull, was ill for two years, and suffered from epileptic seizures of a localized character. These fits had been absent for nine years, but had reappeared and were becoming more severe and more frequent. An operation was performed and a considerable quantity of hard, dense tissue and some softened brain matter were removed. To prevent adhesions between the brain and its coverings and the scalp a square inch of eggshell membrane was inserted between the brain and the skull opening and another piece placed outside over the opening and then the scalp was sutured over all. About four months after the operation following a slight injury the old cicatrix broke down and left a small opening in the scalp through which the second piece of eggshell membrane could be seen, white and glistening. This piece of membrane was removed in its entirety. Its structure had undergone no changes, and under it could be seen granulation tissue. The writer thinks that it was a mistake to insert this second and outer piece of eggshell membrane as it was unnecessary. The cixatrix is good, supple, freely movable and not in the least tender. The patient has had no seizures since the operation.

Changes in Bone Marrow with Leucocytosis.—In discussing the pathological alterations as found in bone marrow as a result of artificially-induced leucocytosis, H. Rubinstein (*Zeitschrft. f. klin. Med.*, Vol. 42, No. 324) concludes as follows: (1) Leucocytosis is an exclusive function of the bone-marrow; (2) after the emigration of the already formed polynuclear leucocytes there is found in the marrow an increased production of large, homogeneous, mononuclear cells which soon show granules and develop into myelocytes;

(3) with a much prolonged leucocytosis, these myelocytes may be stored up in the marrow in such numbers that they form one-half of all the cells; (4) the granular cells develop directly from the large, mononuclear and the granules are basophile in the early stages. This process goes on only in the marrow and never in the blood; (5) the large mononuclear elements develop from small, lymphoid cells which are peculiar to the marrow and distinct from the cells of the lypmh-nodes; (6) the eosinophile cells are formed in a similar manner.

Acute Pericarditis.—According to G. Carrière (*Le Nord Médical*, Apr. 1, 1901) the prognosis depends on (1) its cause; rheumatic pericarditis is fairly benign; that of scorbutus, Bright's disease, pyemia, or tuberculosis is very grave; (2) its nature; dry is not serious, serofibrinous more so, but not necessarily fatal; hemorrhagic is fatal indicating cancer, tuberculosis, or Bright's disease; purulent is usually fatal; (3) the extent of the inflammation; (4) the condition when attacked; it is very grave in old people, in the puerperal state, in alcoholics, the debilitated, the sick or the cachectic; (5) the general effect of the attack; if the prostration is great and the fever high the prognosis is serious; (6) the state of the myocardium; it is well to remember that when life is saved there may be adhesions which subsequently will give symptoms. The main point in diagnosis is the differentiation of the murmur from an endocardial, hemic, or extracardiac murmur. The pericardial murmur is usually superficial, harsh and grating, not transmitted, loudest in the third left space, and mid-systolic or mid-diastolic or both. It is increased by the sitting posture or on pressure with the stethoscope and may be accompanied by friction fremitus. The endocardial murmur is deeper, soft, blowing, transmitted and heard loudest according to the orifice affected, is systolic or diastolic and not changed materially by sitting up or pressure of stethoscope. The hemic murmur resembles the endocardial, but is transmitted only along the vessels, is heard most often and most loudly at base, and is systolic. The extracardiac sound is superficial, soft, mellow, not transmitted, mid-systolic or mid-diastolic, and heard mostly at apex or over left ventricle, seldom in third left space. It is modified by respiratory movements and change of position.

THERAPEUTIC HINTS.

Tuberculous Glands. To avoid unsightly scars, G. B. Massey (*Pro. Phila. Co. Med Soc.*, Mch., 1901) makes a small opening into the gland with a narrow bistoury under ethyl chloride spray, and inserts a sliver of amalgamated zinc to act as the anode of a galvanic current of 1 to 3 milliamperes. This is turned on gradually and maintained for a few minutes till the tract is cauterized and sufficiently impregnated with the oxychlorides of zinc and mercury to keep it patulous for a few days. A gold electrode with amalgamated tip insulated up to ¼ inch from the point is then inserted and 2 to 10 milliamperes turned on for ten minutes and then the wound dressed. Through the sinus thus formed the dead bacilli and deposited chemicals can drain. The treatment is repeated about every three days till the gland has shrivelled.

Pericarditis.—If of rheumatic origin, writes G. Carrière, institute energetic salicylic treatment; if from other infection give quinine as a routine. Keep patient in bed on milk diet. Apply dry or wet cups to the pericardium, or leeches or sinapisms; bleeding, tincture of iodine or vesicatories are harmful. Keep the heart up by digitalis, sparteine, or caffeine. Digitalis should be preferred when the cardiac excitement is extreme, or there is hypotension, or arythmia. The author uses Nativell's crystallized digitalin in dose of ½ to 1 milligram (gr. $^1/_{130}$-$^1/_{65}$). In no disease should the action of digitalis be more closely watched. Never give caffeine toward night, as it increases the nervous excitement and insomnia, but in the daytime it may be given with good result as follows:

℞ Caffeine .....0.50-1.0 (gr. viij-xv)
Syrupi ..... 50. (℥ss)
Sod. benzoat..... 2.0 (℈i-℥v)
Aquæ ..... 100. (℥iij-℥ij)
M. Sig: Gm. 8.0-15.0 (℥ii-iv) at dose.

Sulphate of sparteine is less dangerous than either of the above in dose of gm. 0.01-0.05 (gr. ⅙-$^5/_6$), one to three times a day. The pain and dyspnea may be controlled by injections of morphine. If effusion takes place apply a blister followed by an aseptic poultice. Stimulate diuresis by theobromine, gm. 0.50 (gr. viij), given four times the first day, six the second day, and eight the third, then decrease the frequency. Trional is safe for insomnia. Paracentesis is indicated if the effusion causes pressure symptoms (cough, dysphagia, vomiting, edema, neuralgia), if the pulse is small, irregular, if there is a tendency to syncope or cyanosis, if there is skodaic resonance at the back of the chest, if there is edema of the chest wall, or if the fever is intermittent or continues elevated and the complexion is leaden. Advanced tuberculosis is the only contraindication. Plunge the trocar straight in at a spot 5 cm. (2 in.) to the left of the sternum in the intercostal space just above the lower limit of dulness. Evacuate the fluid slowly, and if purulent wash out with an antiseptic solution, then withdraw the cannula quickly. Pericardiotomy is still in its experimental stage and so far has not given better results. Great prudence is necessary during convalescence; a good tonic would be:

℞ Fl. ext. kola } aa...c.cm 5.0 (ℳlxxv)
Fl. ext. coca. }
Ac. citric,..... gm. 1.0 (gr. xv)
Sod. arsenat .....0.05 (gr. $^5/_6$)
Sig. C.cm. 2.0 (℥ss) each day.

Absorption will be favored by potassium iodide.—*Le Nord Médical*, April 1, 1901.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada

Per Annum in Advance	$4.00
Single Copies	.10
With the American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, APRIL 27, 1901.

THE GRADUATE IN MEDICINE.

The precepts of the old to the young are apt to be uttered either in a spirit of egoism or bitterness. The man who advises another to follow in his own footsteps, with "Never do thus," and "Always do so," implies that his success is a standard, while the man who attributes his failures to some unlucky accident, or unfortunate prejudice against him, or to the injustice of his fellows, has usually a beam in his own eye.

But the temptation to advise is too strong to resist. We who have but recently passed that way remember the slough of despond and see where we took the wrong turning, and it is with the idea of pointing out the safe, sure roads across the field of medicine that we have asked some of the leading men in the profession to prepare the articles of this issue for the students who are graduating in all the medical schools of the country.

The young man fresh from his course where hard work has brought him honors, and where the loafers meet their well-merited reward, suddenly realizes that it is one thing to turn the light of his intellect on and off, at the demand of examiners, and have its quality duly rated in decimal points, and quite another thing to let it so shine before men that they may see his good works.

If he has perception he realizes suddenly what it takes a conceited man a long time to learn, *viz.*, that life is a great game, and that one's education is only acquiring the rules. After graduation the game begins, and all men start practically free and equal. The three-tenths of a point that make the difference between the first-prize man and the second-prize man, or the two points less that meant no prize at all, are as insignificant as the race of the tendrils up a bean-pole. The test is in the beans. Therefore it is well for the successful to nip any propensity to pride, and for the slow to pick up courage, for the success of all is no longer to be measured by calculating professors, but by an unthinking, undiscriminating, but on the whole a very critical public that "knows beans" when it sees them.

The man who is going to succeed is he who adapts himself to conditions as they are instead of going around explaining how they ought to be. If he has a home, a social circle, a certain amount of influence in a far city or country place, he will, if he has good sense, return to it, bringing the results of his medical education to his own people. He may fear that he will always be "Tommy Jones" to them and that they will never let him mend their bones. He does not realize that the very men who pat him condescendingly do so to hide a certain aching regret and envy of the fresh vigor of well-trained youth, and that at his first strike of success his childhood friends will be the most proud of him, and, if he has taken pains to pay his respects graciously on his return, will herald his name abroad.

The man who begins to practise medicine in the city must descend from the dizzy heights of honor he may have attained in his classes, must forget that he is the nephew of the celebrated Dr. Bolus, and on the level plain of present opportunities must take up his line of march. His uncle will perhaps ask him to sit up nights with a wealthy patient, and permit him to give ether at his operations; but he will not risk his own reputation, nor ruin the youngster's chances by recommending him until he has proved himself. And to do this he must not only do minor surgery and write out prescriptions passably well at the clinic, but he must do it very well, as well as if for a millionaire patient, so well, in fact, that his technic, his manner, his interest in the case

will be jeered at, as being a little better than the occasion demands. The present generation, as in the days of Piers Ploughman, has those who "do wel, do bet, and do best"; and it is those who do best who eventually get the reward from the profession if they have any connection at all.

But the modest, average good fellow who has no hopes of distinguishing himself by brilliant work need not despair, for a very good practice may be worked up by a very average man if he be a gentleman. To be a gentleman according to Roycroft philosophy is a fine art. A man who is gentle, generous and kind will disarm criticism and prejudice through the potency of a gracious presence. But books on etiquette will not serve the end, nor studious attempts to smile at the proper time. The words of Hubbard, the sage, are gold to the family doctor, "Your heart must go out to all men, the high, the low, the rich, the poor, the learned, the unlearned, the good, the bad, the wise, the foolish—you must be one with them all, else you can never comprehend them. Sympathy! It is the touchstone to every secret. But knowledge must go with sympathy else the emotions will become maudlin. Knowledge in use is wisdom. Get knowledge by coming close to Nature, listening to her heart-beats, and let your heart go out to humanity by a desire to serve."

Apart from the question of character and environment comes the practical issue that is uppermost in nearly every student's mind, How is he to make his living during the first three years? It is jarring to the pride of a young professional man to realize that he is twenty-five years of age and has barely earned enough to buy his own neckties. But the discomfort is still greater when he finds that, although thoroughly equipped, he cannot find enough paying work to pay his board and office rent, and is obliged to depend on his father for several years more.

It is from this economic point of view that the current issue of the Medical News has been prepared. Every man who has contributed a paper on one of the different ways and means of obtaining a livelihood in medicine writes from the experience that has made him an authority on the subject. It is with no sense of egoistic superiority that each lays down certain principles of action, but with the frank desire to cooperate with us in giving a greeting to the young men who are about to join the profession and to bid them take courage.

The conflicting stories afloat in the profession cause undue hope and depression in the student's mind. The rumor that young Dr. Goldbrick made $7,000 in practice during his first year, by setting up a coach and Japanese servant and doing the swell; the reported confession that the now famous surgeon, Dr. Sawyer, only collected $25 in his first year, and the misleading statistics that the average income from physicians' practice all over the United States is about $900 a year, all have nothing to do with the question of each individual student's success.

We state emphatically that there is a living for every hard-working, well-trained youth who leaves any reputable medical school in the country. It may not be the kind of living that collects a $190,000 fee from a single patient, but it surely will not be a threadbare and down-at-the-heel income.

One thing we beg the young men of the profession to note in all the articles we present, that the men who know believe that honest, efficient work, good sense, and a modest bearing ensure success.

POSSIBLE CONTAGIOUSNESS OF DIABETES.

The most interesting points brought out in the recent investigations of diabetes concern the occurrence of the disease in families. It is easy to suggest heredity and dismiss the facts from the mind as if that suggestion afforded any rational grounds of explanation. Every one of the chronic contagious diseases has at some time in its history been considered hereditary. At the present time there are few biologists who pretend to believe in the direct heredity of any acquired characteristics, pathological or physiological. Moreover, in the case of diabetes the question of the origin of family diabetes is still further involved by the occurrence of marital diabetes. The number of cases that have been reported in which both husband and wife, although of different stock, have suffered from diabetes is entirely too great to think them due to coincidence. As a rule, just as with tuberculosis, the communication of disease seems to be from the husband to the wife. He suffers first and the lowered resistive vitality incident on home-keeping and worry makes the wife a victim.

Conjugal diabetes was at first explained on the score of conjugal syphilis. Syphilis, like heredity, is however an easy word to inject into a discussion on etiology. Especially of

late years when it is claimed by ardent syphilographers that the disease may run an absolutely latent course, it is a simple matter to have recourse to it as an explanation of obscure causation in disease, but this adds absolutely nothing to our knowledge of the subject. With regard to conjugal diabetes, in a number of recorded cases there was absolutely no sign or clinical history of syphilis and no postmortem evidence of the disease's previous existence.

Recent clinical observations point more and more to the conclusion that diabetes may, in some cases, be of infectious origin. Transient glycosuria occurs in many of the infectious diseases. It has been noted, in slight amount at least, in over one-half the cases of whooping-cough. After pneumonia it has been found in some 12 per cent. of cases examined and the presence of sugar in the urine could be detected as long as three months after convalescence had been established. Like albumin in the urine, sugar would seem to occur during the course of many severe infections. The acute diabetes of young children bears all the stigmata of an acute infection.

Despite all the study that has been devoted to the pathology of diabetes there remains a certain number of cases in which no basis of organic change to account for the disease can be found. There is undoubtedly a pancreatic diabetes. There is perhaps a hepatic diabetes. Beyond these cases lie the nervous and so-called hereditary cases for which some explanation is asked.

It has been suggested that the disease is due to the presence of a ferment in the blood which converts the normally latent sugar of the liver and blood into glucose. In this form it cannot be used within the body, but is excreted as a waste product. What the nature of this ferment may be is not known. Supposing its existence, it is easy to see why diabetes attacks husband and wife and often carries off several members of the same family. The possibility of its conveyance by contact is sufficient to cause physicians to warn those in intimate contact with diabetic patients of the necessity for careful precautions as to special cleanliness before food and drink is taken. Of course, this will seem to most physicians absolutely unwarranted. They will scoff at the idea of the contagiousness of diabetes and will talk of the cruelty of making life harder for unfortunate patients by giving publicity to such an idea. It must not be forgotten that a short quarter of a century ago just these same things would have been said about the contagiousness of tuberculosis had anybody even suspected enough about the real nature of the disease to suggest family prophylaxis.

TEMPERANCE PHYSIOLOGY IN THE PUBLIC SCHOOLS.

We are glad to note the signs of revulsion against the extreme temperance reformers, who have by the trick of their laws forced so much namby-pamby stuff into the schools under the head of physiology.

Bugaboo morals are the most childish and the soonest outgrown; and the small men and women who devour with large-eyed horror these exaggerated sentiments about fatty livers and ulcerated stomachs, delirium tremens and cancer of the throat following the use of alcohol or tobacco, quickly learn to discover even the truth in these statements.

We know only too well the means by which very excellent physiologics have been padded to make up the requisite percentage of words upon alcohol and tobacco, under a narrow-minded censorship that struck out every statement concerning the use of alcohol as a useful adjunct in disease; and we have marveled to see the results of scientific investigations deliberately perverted into false generalities.

We deplore the absolute ignorance of American teachers as well as children, concerning the fundamental laws of health, and we wish most heartily that temperance in the matter of eating, of tea- and coffee-drinking, and common sense concerning fresh air, exercise and sleep, as well as the economic value of foodstuffs, might be particularly taught in schools; but so unfair has been this temperance movement, and so great have been the exaggerations perpetrated on an unwary public, that we fear the influence that the schools should have on all matters of public health, including the dangerous effects of intoxicating drinks and tobacco, will be greatly diminished.

Already Western educators are opposing the teaching in its present form, and the Massachusetts Legislature is tightening the reins. Other States are realizing that they are not only being made ridiculous by their laws, but are seriously handicapped by sentimentality; therefore

we hope that the day will soon come when the children will not be forced to swallow pure alcohol for practical physiology.

SAN FRANCISCO'S PLAGUE.

The complete official report of the Commission, consisting of Drs. Simon Flexner, F. G. Novy and Lewellys F. Barker, appointed by the Secretary of the Treasury for an independent investigation of the plague in San Francisco is just to hand in the report of the Marine-Hospital Service.

It confirms the statements already made in the Medical News and serves to accentuate what was pointed out last November in our columns, that there was culpable negligence on the part of some of the health authorities of California in steadfastly closing their eyes to the fact that the plague existed in the Chinese quarter. Now that the true facts are made public in all their significant the thanks of the community are due to the Secretary of the Treasury for the wisdom shown in selecting so able a committee of investigation.

ECHOES AND NEWS.

NEW YORK.

New French Hospital.—The plans for the new French Hospital on Thirty-fourth street, west of the hospital's present site, are now completed and building operations are reported soon to be begun.

Appointment at St. Mary's Hospital.—Dr. J. R. Kevin has just been appointed attending surgeon to St. Mary's Hospital, Brooklyn.

Syracuse Health Board Stops "Rummage Sales."—A halt has been called upon the rummage sale. The Health Board has declared that it is a danger and menace to the community because of its liability to spread disease. For a year women's societies and the churches have reveled in rummage sales, the average being three a day in Syracuse.

Academy of Medicine.—At the stated meeting of the New York Academy of Medicine, to be held at Hosack Hall, May 2, 1901, under the auspices of the Section on Surgery, the general topic will be "The Clinical Aspects of Acute Intestinal Obstruction." Dr. Howard Lilienthal will read the paper and there will be a discussion on special divisions of the subject by Drs. B. Farquhar Curtis, George E. Brewer, Charles L. Gibson, Morris Manges, Henry Koplik and others.

Diphtheria Epidemic in Highbridge.—To prevent the spread of diphtheria, which is epidemic in Highbridge, Public School No. 91, the only school in the place, was closed last week by order of the Health Department.

Tuberculosis Hospital Commission.—The Committee on Rules of the Assembly April 18th amended Senator Davis's bill for the construction of a State Hospital for Consumptives in the Adirondacks so as to provide that the Commission to review the selection of the site shall consist of the Governor, the Speaker *pro tem* of the senate, and Speaker Nixon of the Assembly.

Consumptives' Hospital Trustee.—Governor Odell has named Norman S. Dyke, of Brooklyn, as a member of the Board of Trustees of the State Consumptive Hospital, in place of Walter Jennings.

Course in Bacteriology for Physicians.—The Department of Bacteriology of the New York University and Bellevue Hospital Medical College desires to announce that a short practical course on bacteriology will be given in the Carnegie Laboratory during April and May. The course will begin on Monday, April 29th. There will be given on alternate days a series of three-hour exercises on laboratory technic and the practical application of bacteriology in the prevention, diagnosis and treatment of disease. Physicians who have had some training in bacteriology and who do not desire to spend the time required for the whole course may select one or more of the exercises devoted to the consideration of special subjects. They may thus refresh their knowledge on those subjects of special interest to them and at least learn what assistance bacteriological examinations may afford in clinical work, the methods for the preparation of material for laboratory examinations, and the interpretation of results. The exercises will begin at two o'clock and will continue until five. The first six exercises will be devoted to bacteriological technic and must be taken together. The subjects for the last eight exercises and the dates for each are as follows:

May 13, 1901—The diphtheria bacillus and diphtheria antitoxin.

May 15, 1901—The tubercle bacillus and tuberculin.

May 17, 1901—The typhoid bacillus and the serum reactions.

May 20, 1901—The gonococcus, the pneumococcus and the streptococcus.

May 22, 1901—Examinations of water, ice and air, and their value.

May 24, 1901—Examinations of blood, urine, feces and milk.

May 27, 1901—Disinfection.

May 29, 1901—Miscellaneous.

Those desiring to take the entire course or only a portion of it are requested to notify Dr. Egbert LeFevre, Secretary of the Faculty, prior to April 25th, so that suitable arrangements for their accommodation may be made.

The charge for the fourteen lessons will be $20. The charge for single exercises will be $2 each. Microscopes, apparatus, culture media, etc., will be furnished. The courses will be under the direction of Dr. Wm. H. Park, Professor of Bacteriology and Hygiene, assisted by Dr. Robert J. Wilson, Dr. H. H. Brooks, and Dr. R. H. Bebb, Assistants in Bacteriology.

PHILADELPHIA.

New Clinical Amphitheater for the University of Pennsylvania.—A gift of $25,000 has been made to the University of Pennsylvania by Mrs. C. B. Newbold for the construction of an obstetrical amphitheater. The new building will be 50 feet square and will accommodate 150 students. It will be known as the Scott Amphitheater, in memory of Mrs. Newbold's mother.

Resignation of Dr. Risley; His Successor.—Dr. Samuel D. Risley has tendered his resignation as Professor of Ophthalmology at the Philadelphia Polyclinic and College for Graduates in Medicine. As a mark of appreciation of his services the Trustees, after accepting his resignation, created the position of Emeritus Professor of Opthalmology and made him its first incumbent. At the same time Dr. William Campbell Posey was chosen to fill the vacancy caused by the resignation of Dr. Risley. Dr. Posey is a graduate of the University of Pennsylvania and since studying abroad has held positions on the staff of the Howard, Epileptic, and Wills Eye Hospitals, and the Home for Incurables.

A Large Fee.—Probably the largest physician's fee ever asked in this State is the bill presented by Dr. Walter C. Browning, of this city, for his services to the late Senator C. L. Magee of Pittsburg. The bill is for $190,000 and is for professional services rendered during a period of twenty-one months. There is included $17,000 for a trip to Atlantic City with the patient and also $12,000 for similar attendance at Hot Springs, Va. Local papers quote Dr. Browning as saying that Mr. Magee voluntarily doubled his night charges of $40 per hour and told him to charge $80. The charges for the trips mentioned are computed at that rate. The executors of the Magee estate claim that the charge is exorbitant and that no monthly bills have been found among the effects of the deceased. The bill will in all probability be contested.

The Corset for Movable Kidney.—Dr. A. Ernest Gallant of New York read a paper on the above subject at the Section on Gynecology of the College of Physicians April 18th. Dr. Gallant claims that from 90 to 95 per cent. of symptomatic movable kidney can be symptomatically relieved by the proper use of a corset. He states that movable kidney is quite a common condition. To determine its frequency, examination for it was made in 1,900 gynecological cases seen in dispensary work and private practice, with the result of finding 41 cases of movable kidney. Of these, 25 had both kidneys movable. The amount of suffering does not depend on the degree of mobility, those cases in which the kidney is at the pelvic brim as a rule giving the patient the least trouble. Dr. Gallant believes that fixation of the movable kidney often does not accomplish all that is desired, while mistakes in diagnosis make the surgeon hesitate at times to operate. Belts and pads have their disadvantages and as women persist in wearing corsets it is better to teach them to wear the corset properly than to try to induce them to give up the habit.

The Technic of Applying the Corset.—The corset for holding a movable kidney in place should be as long in front as can be worn and two inches smaller than the size usually worn. It should be laced from the bottom upward and while this is being done the abdominal wall should be drawn upward as much as possible thus making the corset act as a support when tightened. Before the upper end is fastened the kidney should be pushed well up beneath the ribs. The corset should be put on before the patient rises each day and should not interfere with walking or expansion as this method prevents tight lacing at the waist. When there is tenderness of the organ the patient should be put in bed a few days, given a light diet, massaged, etc., before the corset is applied. Careful attention to the general health of the patient is needed in all these cases.

An Interesting Case of Trichinosis.—This case was exhibited by Dr. J. Chalmers Da Costa at the Neurological Society April 22d. The patient is a male, twenty years of age. There is a history or traumatism on the calf of the right leg by a bicycle pedal in August, 1900. After that the patient changed his residence and ate pork about four times a week, but not raw pork, and at times raw beef. Since January 1, 1901, the right gastrocnemius has been swelling and causing pain at night. The thigh is also now involved, the swelling being marked. Examination of a bit of excised muscle shows the presence of very numerous trichinæ. Several blood examinations have been made, the largest number of eosinophiles being 4 per cent. The leucocytes have increased from 12,000 to 20,000. The case is notable for the entire absence of the symptoms usually belonging to trichinosis.

CHICAGO.

Appointment of Dr. Peterson.—Dr. Reuben Peterson, President of the Chicago Gynecological Society, has been appointed Professor of Obstetrics and Gynecology in the University of Michigan, at Ann Arbor, to succeed Dr. J. N. Martin.

Transfer of Rush Medical College Students.—Hereafter the students of this college will do their first two years' work at the University of Chicago. President Harper has just received a gift of a large sum of money with which to provide the additional facilities needed to accommodate the three hundred students who will be transferred in a body by the new arrangement. The amount of the gift is known to be between $50,000 and $100,000. The name of the donor is withheld. The new arrangement will go into effect on July 1st and will add about three hundred names to the undergraduate roll of the University. The present Freshmen class at Rush will become part of the Sophomore class at the University, and first-year students who matriculate for the medical course will enter the University at once. Several members of the Rush Faculty also will be transferred, and additional teachers will be added to the staff of the University. The Junior and Senior medical classes will continue to do clinical work at the present location, adjacent to the Presbyterian and Cook County Hospitals, and quarters will be provided for them in the building now being erected at Harrison and Wood streets at a cost of $110,000.

Smallpox.—There have 175 cases of smallpox found in this city between November 30, 1900, and April 13, 1901, the period of the present epidemic. Of this number 143 had never been vaccinated. Of the remaining 32 cases, 30 were adults showing faint, poor or irregular scars, claimed to be evidence of attempted vaccination in infancy or early childhood, the most recent being twenty-three years old. Only two out of the 175 cases exhibited typical scars of successful vaccination. Of these 1 was thirty-five years old, vaccinated when a child, revaccinated attempted three years ago without results, vaccine lymph probably inert. The other was forty years old, also successfully vaccinated in childhood, but never revaccinated. These are the only two cases out of the total 175 on whom vaccination was ever successfully attempted, and the most recent of these was more than thirty years ago. This shows conclusively that successful vaccination in childhood and successful revaccination after are the only sure safeguards against smallpox.

Drainage Canal.—Contention of members of the Drainage Board that a reduction of the flow of water in the drainage canal in accordance with the orders of the War Department would threaten local sanitary conditions, were exploded recently by Commissioner-of-Health Reynolds. Dr. Reynolds declared the present dilution of sewage in the canal was beyond present practical sanitary requirements, as only a relatively small portion of the city's sewage was being disposed of through the canal. He added that the reduction of the flow from 300,000 to 200,000 cubic feet a minute would give no occasion for immediate fears as to Chicago's sanitary condition. Charges were made, too, by a number of drainage trustees that the reduced flow problem has been used as a club by those members of the Board who have fought for the passage of bills now pending before the Legislature by which an extra tax was sought by the sanitary district for the work of widening the river. As a result, the bill calling for an additional tax of one-half of one per cent. to carry out this plan is expected to fail of passage.

Investigation of Cook County Hospital.—Complaints and charges have been made that patients are subjected to abuses and unnecessary pain at the clinics at the Cook County Hospital. An investigating committee of thirteen has been appointed and is now listening to evidence for and against the conduct of the institution. Many of the charges are without foundation. We shall await with interest the final report of the investigating committee.

Some Forms of Meddlesome Obstetrical Practice.—At a meeting of the Chicago Medical Society, held April 17th, Dr. J. Clarence Webster read this paper in which he confined himself to three topics, namely, misuse and abuse of antiseptic douches, digital examination, and forceps. Too strong a protest cannot be urged against the indiscriminate and unscientific use of antiseptic vaginal douches in obstetric practice. There has been much difference of opinion among workers as to the normal condition of the vaginal contents, but the causes of their differences have been recently fairly well elucidated, and at the present time it may be accepted as proven that the genital canal tends to be maintained in a state of asepticity by natural means. Prophylactic douching in pregnancy is unnecessary; neither is it necessary after labor, if the woman is not exposed to contamination by those who attend her during parturition. Given a sterile genital canal, the aim should always be to conduct the labor aseptically. Nothing is more to be deprecated than the routine vaginal examination of parturient women in practice. It is absolutely unnecessary in the great majority of cases. The abdominal examination is ordinarily a sufficient source of information to the physician. There are occasions when vaginal examination is necessary. Then it should be made with as much care as is exercised in the best technic of surgical operations, not in the hasty and careless manner only too frequent in ordinary practice. As regards after-douching, in the majority of cases it is not necessary. Where there is a tendency to the accumulation of blood-clots in the vagina, simple salt solution may be used.

There can be little doubt that since the introduction of anesthesia into obstetrical practice artificial delivery by various procedures

has become very much more frequent than in the pre-anesthetic days, when interference was avoided as much as possible because of the increased sufferings of the patient. It is too often forgotten that the majority of labors are natural, that they should be interfered with as little as possible, and that interference even by the most skilled hands is always accompanied with risks. Forceps operations are undoubtedly undertaken with too great frequency. The writer gave statistics regarding the frequency with which forceps are used in various European hospitals.

Gynecological and Obstetrical Significance of Girlhood.—Dr. Henry P. Newman read this paper. He said that the girl as the product of modern civilization is, in everything but bodily vigor, removed by all that is desirable from her aboriginal mother. It is the just aim of our educational system to develop still further her intellectual advantages, but it is also due to her and to the vital interests she represents that we restore to her as far as is possible to modern society the physical advantages of which our multiplication of artificial standards has deprived her. Her muscular activities are curtailed by the adoption of the corset and a more mature and burdensome form of dress; her social instincts are aroused by too early participation in exciting amusements and with it all she begins to experience the nerve-trying influence of the menstrual epoch. If employed as a wage-earner, the conditions of her occupation are even less favorable as a rule. In a very large per cent. of American girls there is greater or less impairment of the menstrual function. Some of the results of improper hygiene of the developmental period of puberty are menstrual pain and nervous exacerbations, chronic congestion, inflammations, extension of the tubes and ovaries, invalidism, difficult labor, trauma in childbirth, sterility. Of most value in the premises is prophylaxis; it is much easier to prevent such evils than to remedy their effects. Mothers and educators, with the intelligent cooperation of the girl herself, can do much to better the conditions. Outdoor life should be as rigidly insisted on for the girl as for the boy. The dress should be as free and unconfined as his. Forced mental development at the expense of the physical should be discouraged. Where the local mischief has already been done the indications are to relieve pain and restore as far as possible the normal relations of the pelvic organs.

GENERAL.

New Boston Hospital.—Provisions for a new hospital for Boston are made in the will of the late George L. Thorndike of East Boston. He directs that after the death of the last legatee under the will, and when the estate exceeds $200,000, it be used to build a hospital. He also gives the city $10,000 in trust, the income of which is to be used to purchase coal for distribution among the widowed women of East Boston.

Doctors' Strike Fails.—The physicians employed by the sanitary authorities at Leipsic, who recently went on strike in a body for better conditions of employment, have been supplanted by other physicians, in need of employment, from Berlin and other cities.

St. Paul Meeting and Yellowstone Park.—Arrangements have been completed for an excursion of the members of the American Medical Association to Yellowstone Park. The Committee of Arrangements has finally succeeded in persuading the officials to open up the park a week earlier than usual in order to accommodate the Association. A special train will be run from St. Paul to the Yellowstone Park and the railroad officials have promised to do everything in their power to make it satisfactory to all concerned. The rates will be very low, but how low cannot at this time be definitely stated. Those who attended the meeting in 1882 will remember with much pleasure a similar excursion that was run at the time, and these will not need to be informed that the one now proposed will be full of enjoyment. Further announcements will be made later. The Yellowstone National Park contains more natural wonders than are to be found anywhere else in the world, and this will be a rare opportunity for our Eastern friends to see what this portion of our Great West possesses. Address editor of Medical News for further information.

Discovery That Means Food.—The *New York Sun* says editorially: "We learn from a competent authority that one of the latest developments in electrothermis is the synthesis of oxides of nitrogen from atmospheric air. The importance of such a discovery to the world at large cannot Crookes, when President of the British Aswell be overestimated. It will be remembered that some years ago Sir William sociation, called attention to the rapid diminution of the world's supply of nitrates and pointed out their enormous importance as fertilizers in increasing the productivity of the soil. Sir William Crookes maintained, and his conclusions have been to a considerable extent accepted by scientific people, that the areas of the earth that could be devoted to wheat culture were rapidly decreasing, and that unless some means could be discovered of making them produce more wheat than they do now, the growing population of the world would within a comparatively short period cause the consumption of this great foodstuff far to exceed the supply of it. Nitrogen, of course, is the base of all fertilizers, and while there are not in existence natural beds of nitrate deposits in anything like sufficient quantity to supply fertilizing material for the purpose indicated, Sir William Crookes pointed out that if a method of "fixing" atmospheric nitrogen could be discovered it would solve the difficulty. If this method has now been found we have before us one of the

greatest booms that have ever come to the human race. Cyanide of potassium is also one of the practical achievements of this new discovery and its use in the industrial arts is of widespread importance, especially in the economic separation of gold. As for the nitric acid thus made, it is absolutedly pure, of standard specific gravity and is produced for one-eighth of the cost of the nitric acid of commerce. The new century starts out with no abatement of the marvelous speculative energy that so diminished its predecessor. And electrometallurgy is still absolutely in its infancy."

Emergency Building for Ann Arbor.—At least $370,000 is required for the new buildings for the University of Michigan and for improvements in old buildings. A year ago the Board of Regents had plans drawn for a $300,000 Science Hall, which would bring together all branches except chemistry and physics under one roof, but the Auditor-General of State, owing to the small legislative appropriation, now says that the university must have funds before warrants will be honored, as the regents cannot draw upon future appropriations. The general plan of the building will not be abandoned, but to relieve the overcrowded condition of the medical department, a building will be erected near the present one, which will accommodate the bacteriological and histological laboratories. It is to cost $100,000. Work will begin next summer.

American Gastro-Enterological Association.—The fourth annual meeting of this association will be held in Washington, D. C., Wednesday, May 1, 1901. The following program is announced: "Syphilis of the Liver," by Dr. Max Einhorn; "The German Clinics of To-Day," by Dr. J. C. Hemmeter: "Etiology of Hepatic Sclerosis," by Dr. A. L. Benedict; "Treatment of Gastric Ulcer," by Dr. D. D. Stewart; "The State of the Gastric Secretion in Chronic Rheumatism and Rheumatoid Arthritis," by Dr. Frank H. Murdoch; "Some Cases of Tetany," by Dr. Wm. Gerry Morgan; "The Report of Two Cases of Acute Dilatation of the Stomach," by Dr. Julius Friedenwald; "Experiments in Peristalsis," by Dr. Fenton B. Turck; "Some Clinical Studies in Gastric Secretion," by Dr. G. W. McCaskey; "Treatment of Atonia Gastrica and Splanchnoptosia by means of Abdominal Strapping," by Dr. R. Rose: "Hyperchlorhydria," by Dr. John A. Lichty; "Report of a Case of Cancer of the Cardiac End of the Œsophagus at a Distance of Twenty-one Inches from the Incisor Teeth in a Man Five Feet and Three Inches Tall," by Dr. C. D. Spivak, and "Spastic Ileus," by Dr. Edward Quintard.

Louisiana State Medical Society.—The last annual meeting of this Society took place last week in New Orleans, April 18th, 19th and 20th, at the Medical Department of Tulane University. The program was extensive and interesting. Among the subjects discussed were: "Treatment of Fractures of the Long Bones" by Dr. E. D. Martin; "Treatment of Cystitis" by Dr. Chas. Chassaignac: "Proprietary Medicine Prescribing" was ably discussed before the Section on Materia Medica and Therapeutics, by Dr. L. Sexton, chairman; and a paper on "Middle-Ear Complications of Childhood" was read by Dr. O. Joachim; "Lacerations of the Cervix and their Consequences," were among the subjects taken up by the various Sections.

Other papers were: "Over-action of the Heart from Administration of Hyoscin," by Dr. Parsons, of Minden, La.; "Thirty Cases of Acute Lobar-Pneumonia, with Twenty-nine Recoveries" by Dr. Edward D. Newell, St. Joseph, La.; "Otitis Media Neonatorum" by Dr. O. Joachim, New Orleans; "Affections of the Nose and Throat as Factors in Diseases of the Bronchi and Lungs" by Dr. W. Scheppegrell, New Orleans; "Uses of Strychnine" by Dr. J. M. Barrier, Delhi; "Potassium Iodide and Mercury in Syphilis of the Negro" by Dr. A. Guilbeau, Breaux Bridge; "Clinical Test of Sodium Cacodylate" by Dr. E. M. Dupaquier, New Orleans: "Alcohol and Digestion" by Dr. J. A. Storck, New Orleans; "Vital Statistics in Louisiana" by Dr. G. Farrar Patton; "Science and Pseudo-Science in Medicine" by Dr. T. S. Dabney; "Symptoms of Extra-uterine Pregnancy" by Dr. C. J. Miller; "Contagious Diseases" by Dr. C. L. Horton; "Ptomain-poisoning in Children" by Dr. L. G. Le Beuf; "Spinal Analgesia" by Drs. S. P. Delaup and F. W. Parkham: "Disinfection from a Practical Point of View" by Dr. John J. Archinard; "Malarial Polyneuritis" by Dr. C. J. Gremillion and "A Case of Abdominal Pregnancy" by Dr. A. G. Sterling.

Director of the Bureau of Bacteriology and Pathology.—Commissioner Daniel Lewis of the State Department of Health has appointed Dr. George Blumer of the Bender Laboratory of Albany Director of the Bureau of Bacteriology and Pathology, which is a new department.

Columbia Honored.—Columbia has been honored by the election of two more members of its faculty to the National Academy of Sciences. The membership is limited to one hundred. Last year of the four members elected two were Columbia men. This year the Columbia professors chosen are James McKeen Cattell, Ph.D., professor of psychology and anthropology and T. Mitchell Prudden, M.D., LL.D., professor of pathology in the College of Uhysicians and Surgeons.

Medical Jurisprudence Society.—The Society of Medical Jurisprudence held its eighteenth annual meeting and dinner at the Waldorf-Astoria last Saturday. Toasts were responded to as follows: Judge William J. Gaynor, "The Future of the Municipal Government and the Doctor and the Lawyer in It"; ex-Attorney General John W. Griggs, "The United States Supreme Court"; the Rev. Father Thomas Ducey, "The Mission of Justice and Mercy"; Tom L. Johnson, "Com-

ing Issues"; Judge Henry A. Gildersleeve, "Thoroughness in the Profession"; William M. Polk, M.D., "Lawyer and Doctor"; Charles W. Dayton, "Facts and Expert Testimony"; Martin W. Littleton, "From the Diary of a Public Prosecutor." The President, Frank Ferguson, M.D., presided.

Obituary.—Dr. Almon V. Belding, ninety-four years old, of Rochester, N. Y., died on Thursday night in that city. He was born in Phelps, N. Y., and came to Rochester in 1867.

Professor Kohlstock, the rinderpest and cholera investigator, died last Monday at Tientsin. He died from disease contracted during his investigations.

Dr. H. S. Scruggs, one of the best-known physicians of Tennessee, was assassinated April 17th, while returning from a professional call. Dr. Scruggs was a school director and had trouble with the patrons of a school on account of an order promulgated requiring parents to send written excuses to teachers when their children were absent.

Dr. Frederick J. Brockway, late of 153 West Seventy-third street and 437 West Fifty-ninth Street, New York City, died of meningitis at Brattleborough, Vt., this week. Dr. Brockway was born in South Sutton, N. H., February 24, 1860. He received the degree of Bachelor of Arts from Yale, and his medical degree from the College of Physicians and Surgeons, in which institution he was an Assistant Demonstrator of Anatomy as well as Secretary of the Faculty. He was a member of the American Museum of Natural History, the New York Academy of Medicine, New York Academy of Sciences, the Alumni Association of Roosevelt Hospital, the New England Society, and the New York Athletic Club. He was a son of John G. Brockway of Contoocook, N. H., and a nephew of H. H. Brockway, the proprietor of the Ashland House, this city. A widow and two daughters survive him.

Dr. Louis Philip Fontaine died at his residence, No. 109½ East Fortieth Street, New York City, last week, from Bright's disease, after an illness of several months. Dr. Fontaine was born in France, and came to this country forty years ago. He was sixty-nine years old. He was married, but childless.

Dr. Joseph S. Carradine, who died in East Orange Tuesday, and whose office was at 45 West Twentieth Street, came from a Mississippi family and was graduated from the Pennsylvania Medical College in 1858. He was a member of the County Medical Society and the County Medical Association, and was a brother of the Rev. Dr. Beverley Carradine, who, while pastor of a prominent Methodist Episcopal Church in New Orleans, was among the first to raise his voice in denunciation of the Louisiana Lottery and start the crusade which finally compassed the fall of that corporation.

Dr. Edward Watts Morris, an eminent physician in North Alabama, died at Birmingham Tuesday, at the Morris and Lumpton Infirmary, of pneumonia, aged thirty-six years. He was a native of Virginia, and graduated in medicine in that State, practising first in Richmond. He went to Birmingham sixteen years ago.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 13, 1901.

THE REFORM OF THE ARMY MEDICAL SERVICE—CAUSES OF THE DOCTORS' DISCONTENT—THE ANTAGONISM OF LORD WOLSELEY, THE DUKE OF CAMBRIDGE AND SIR REDVERS BULLER—THE UNPOPULARITY OF THE SERVICE—MILITARY TITLES FOR MEDICAL OFFICERS—THE COLLAPSE IN SOUTH AFRICA—CRITICISMS ON THE ROYAL ARMY MEDICAL CORPS—A "DRASTIC REFORM" PROMISED.

Another matter now exciting keen interest in the profession here is the question of reform of the medical service of the army. For many years past those who knew the real state of things have foretold that in a war of any magnitude our medical service must inevitably break down. Again and again it has been urged on the War Office that the medical staff was undermanned and consequently overworked, and that the officers had no opportunity of keeping themselves abreast of the progress of medical science. But the War Office paid no heed to these warnings, and the state of the service went from bad to worse. The military authorities persisted in regarding the doctors as civilians whose relation to the army, as Lord Wolseley elegantly put it, was that of "camp followers." The late Commander-in-Chief lost no opportunity of showing his contempt for medical officers—a feeling all the more remarkable in him that one of his own brothers was an army doctor. At a parade in Dublin when the men of the Army Medical Staff with their officers stood before them with drawn swords in accordance with military regulations he angrily ordered that the weapons should be sheathed as "these men are not soldiers." He said in his "Soldier's Pocket-book" that medical advice is a good thing—when it is asked for; and that it might not be thrust upon him in Egypt he stationed his Principal Medical Officer as far as possible away from headquarters. Lord Wolseley in the same manual scoffs at the idea of having a special Sanitary Officer, whom he calls a "fifth wheel to the coach."

The disastrous epidemic of typhoid fever among the troops in South Africa may fairly be regarded as the practical outcome of this attitude of mind in the late Commander-in-Chief. Had there been a Sanitary Officer with Lord Roberts in his march to Pretoria, it is probable that the outbreak might have been checked at the beginning, or at any rate prevented from becoming the devastating scourge which, more than the "slim-

ness" of the Boers or the blundering of our generals, has been the cause of the prolongation of the war.

The Duke of Cambridge, who was Commander-in-Chief before Wolseley, was also unfriendly to the doctors. It is on record that His Royal Highness's life was saved in the Crimean War by an army surgeon who by a deed of the most daring courage extricated him from a mass of Russians by whom he was surrounded. The Duke's nerves were so shaken by his adventures on the field of Inkerman that he soon after got leave to attend to "urgent private affairs" in England. The incident referred to perhaps created in his mind an unpleasant association with army doctors. At any rate he always showed a special dislike of them afterward. Before a Royal Commission which inquired into the state of the service some years ago, the Duke's language with regard to them was of such a character that it was not considered advisable to publish it in the Report. Some of the evidence given by Sir Redvers (or Reverse) Buller on the same occasion was also suppressed. The Charon of the Tugela is reported to have expressed the opinion that it is right that medical officers should be systematically blackballed at military clubs, as they are unfit to be admitted to the company of the noble warriors who growl and grumble and fight their battles o'er again in those establishments.

This being the spirit which animates the War Office in its dealings with the medical officers of the army, it is scarcely to be wondered at that the service has become more and more unpopular with the younger members of the profession, till now there are practically no candidates. Such as do present themselves at the periodical examinations for admission to the Service are for the most part, to use a phrase of John Bright's, the *residuum* of the medical schools. This has been the case for a long time past. Twenty-five years ago the service was left almost entirely to men from the Irish and Scotch schools; the feeling of English students was like that of John Abernethy as to the corresponding service of the navy. When Richard Owen had finished his studies he went to take his leave of Abernethy who asked him what he was going to do. On Owen's replying that he was going to sea, Abernethy exclaimed "Going to sea! As well go to the d——l!" No one with any chance of making a livelihood in civil practice would have dreamed of entering the army. The result was that the service was recruited from a class of men who were no credit to their profession. Army doctors became a byword for ignorance. I remember one candidate who at his clinical examination was puzzled by a case of torticollis. He afterward asked one of the resident officers of the hospital what it was, and on being told said he supposed the disease was called after the great Colles of Dublin! Cases of the simplest character used to be sent to general hospitals by commanding officers of regiments, with the explanation that they were beyond the professional skill of the army doctors. All this was long before the relations between the combatant and the medical officers became embittered by the demand of the latter for military rank and titles. The pay and status of the army doctors were gradually improved by successive concessions—all wrung from the War Office by the force of circumstances—and three years ago the late Secretary of War, Lord Lansdowne (himself by the way a descendant of Sir William Petty who was Physician-General to Cromwell's army in Ireland) granted the titles which had been obstinately refused by the military authorities before. The army doctors were made officers of a Corps (Royal Army Medical Corps) with purely military titles and with command of the men of their Corps. This satisfied the doctors for a time and it was hoped that the service would attract a better class of men. The medical Colonels and Majors, however, were looked upon as counterfeits by the military officers, and many civilian practitioners did not care to see their brethren masquerading in plumes matching ill with the sober cloth of their profession.

All this must be taken into account in estimating the extent to which the army medical service has broken down in South Africa. The jealousy which the military titles have excited has added venom to the attacks which have been made on its work. It is clear enough that many of its critics are rejoiced that it has failed, and this unpatriotic and unphilanthropic sentiment is founded on a mean spite which betrays itself in many anonymous letters which have appeared in the papers as well in the dithyrambic maledictions of Mr. Burdett-Coutts. The true inwardness of this gentleman's onslaught is that he is the spokesman of a band of society ladies who went out to South Africa as ministering angels, but had their wings tied up with red tape, whereat they not unnaturally felt aggrieved. To avenge their wrongs they instigated a "campaign of calumny."

In Parliament members of the Opposition have found in the misfortunes of the Royal Army Medical Corps many weapons that could be used with effect against the Government. The political element must especially be allowed for in determining the exact significance of Sir Walter Foster's criticisms of the medical management of the war. Soon after the beginning of the campaign he patriotically offered to go out to South Africa as a Sanitary Commissioner, and he is inclined to attribute the calamities that have occurred to the refusal of his offer.

When the most liberal discount, however, has been made for these various sources of fallacy, the fact remains that the medical service of the army has broken down, and that this is not fully to be explained by undermanning or even by military titles. The system is bad, promotion being almost entirely by seniority, and initiative being everywhere paralyzed by red tape. Moreover, the standard of professional skill among the officers of the R. A. M. C. is far from what is should be.

Mr. Broderick the present Secretary of State for War was promised a "drastic reform" of the service. It is very doubtful, however, whether he will succeed, for the tone of his utterances on the subject of military titles and other points has so far been distinctly unsympathetic. He is a self-confident man and is credited with the intention of working out a scheme of reform entirely his own. But he will have to reckon both with the medical profession, which will accept no scheme detrimental to its dignity, and with the public which is determined to have a medical service adequate to the needs of its soldiers. One thing is certain, and that is that if the government wishes to get medical officers of the right sort it must pay them liberally, give them the position and authority required for the efficient discharge of their duties, and provide that they shall have abundant opportunity and ample encouragement to improve their knowledge and perfect their skill.

CHLOROFORM-OXYGEN COMBINED ANESTHESIA—PRIMARY SYPHILITIC CEREBRAL ENDARTERTIS—CHRONIC ARTHRITIS — NEURITIS — PHRENIC HERNIA—POSTMORTEM CÆSAREAN SECTION—TYMPANIA UTERI—INHALATION DISEASES.

Aronson explained the recent favorable results obtained by Wohlgemuth in giving combinations of oxygen and chloroform for anesthesia. At Zuntz's laboratory Aronson has himself during the past several years made use of such a combination in experiments on animals. Pushed to the fatal point, the oxygen appeared not to have the least possible influence in saving the animals. On theoretical grounds Zuntz has himself condemned its use in practice. The reason Wohlgemuth has had better success lies in the fact that he delivered the oxygen under pressure, thereby securing its better combination with the chloroform. Further experiments show that compressed air similarly combined with chloroform is just as efficacious.

Heubner presented the brain of a two-and-a-half-year-old child which had presented the symptoms of a cerebral paralysis and shown a recurrent right-sided muscular paresis. The lesion was a vast primary syphilitic endarteritis affecting the base of the brain particularly, and causing as a secondary phenomenon through faulty nutrition a microgyria of one hemisphere which did not have as accompaniments any marked softening or gummata. During life there was apparent a right-sided syphilitic retinitis of hereditary origin. He also presented an eleven-year-old girl who presented a general chronic arthritis of all the joints, practically, which had gone on to more or less ankylosis, even of the vertebral column and caused retarded and imperfect development of the under jaw. The etiology appeared to depend entirely upon choreic attacks in earlier life. His next patient was a child ten years old with a general neuritis and paresis of the extensors of the feet without any affection of the sensibility. Here again choreic intoxication was very probably the cause.

Widenmann brought before the meeting a forty-year-old man who had had since early youth a hernia through the diaphragm into the left thorax. It appeared to give him no especial symptoms except that during the past year, he had suffered from temporary signs of incarceration. Examination showed part of the left lobe of the liver, and almost all of the stomach herniated into the thorax thereby causing physical signs of pneumothorax. What the cause of the hernia had been, it was impossible to determine.

Gessner, at the Aertzlicher Bezirksverein zu Erlangen, January 28, 1901, described an example of postmortem Cesarian section which resulted in a living offspring. The primipara had had a large amount of albumin in the urine during her pregnancy and died during the initial eclamptic seizure, which itself had not been seen by him. Within ten minutes after death the section was done and a very deeply cyanosed child obtained. After about two hours' hard work it was fully resuscitated and left in good health. The emptied uterus contracted down a great deal and really forced the placenta up into the wound. The uterus and placenta were removed and hardened. On longitudinal section it was found that the placenta in this case did not separate centrally from the uterine wall, but though bulging forward was still firmly attached. This is contrary to the teaching of many authorities, who hold a central separation is the first step toward the discharge of the afterbirth.

The same speaker read the paper of the evening on tympania uteri. This he stated is a condition which the text-books are apt to neglect or treat lightly and too indefinitely. Its prognosis based upon the old syndromata for diagnosis and the old statistics is very poor. Naturally the condition is far more common than was once supposed and practically only the frank clear cases are those which are recorded, because others often escape diagnosis altogether. The old belief that tympania uteri depends upon the entrance of bacterium-laden air into the uterus is according to the researches of Gebhard erroneous. The underlying factor is infection by the bacterium coli. Other observers claim that anaerobic pus may also be the cause. The first step of this condition appears to be foul-smelling or putrid liquor amnii. The clinical picture is a various one. In the majority of cases the fever is a purely absorption fever, due to the entrance into the system of the products of cell activity and decomposition of the elements of the liquor amnii. Consequently it appears a variable time after the swelling of the organ and usually disappears when it is emptied and cleansed. In a minority of the cases one finds various severe recurrent febrile manifestations throughout the puerperium. Such are due to infection of the genital tract with the pyogenic micro-organisms from without, in addition to

those already present in the uterus. Supposed air-embolism of the uterus had best be ascribed to sapremia with anaerobic germs as the cause. Feeble pains may easily appear in tympania uteri, especially when the distention by gas has been at all marked. In such patients we may look for atonia uteri in the puerperium, particularly just after delivery. Bad cases of this condition are to-day much more rare, because the diagnosis is made at an earlier date and the causes are better known. Tympania is more common among primiparæ because of their aptitude to carry the child over time. A narrow pelvis contributes and an early rupture of the membrane definitely exposes the mother to it. At the present time the prospects for the mother are better than formerly, in the ration of 50 per cent. of deaths under the old statistics to about 12 per cent. in the new. Similarly the child is better off. Neither the height of the fever nor the pulse-rate permit of any conclusions as to the ultimate outcome, but a decidedly unfavorable sign is the occurrence of chills early in the onset of the disease, because in such cases severe sickness during the puerperium is likely. The treatment of tympania uteri is to be begun just as soon after delivery as possible. Formerly vigorous intra-uterine douches were in vogue, but have latterly been abandoned because they appear to induce chills, which forerun serious complications.

Saenger, at the Medic. Gesell. zu Magdeburg, January 16, 1901, deliberated on the cause underlying the diseases usually ascribed to the inhalation of dust. The penetration of dust-particles in the deeper and deepest air channels of the whole respiratory tract must be a very difficult matter indeed, because there are so many normally disposed bars to it. The bronchial tree itself is composed of many canals variously and complexly curved upon themselves and placed more or less at angles to each other, while the caliber steadily decreases beginning with the trachea. To assume that dust-particles move along the axis of such a tortuous system of passages, whether the force be expiratory or inspiratory, is undoubtedly an error. As a matter of fact the dust probably impinges more or less constantly upon the walls at each turn and more especially upon the convexity of the curves. Such a path for it is therefore a resultant of the bend in the canal itself and its effect upon the dust-bearing currents. Thus it happens that the vast bulk of the dust in an air current rapidly comes into contact with the convexities of these tortuous channels and in a very devious route practically all of it meets the walls and, if these are moist, of course adheres when, as in the lungs these turns and angles are wonderfully multiplied, it soon follows that all the dust remains clinging to the walls. In a very similar way a long gradually narrowing tube tends to promote a deposit of dust upon its walls out of a current of air passing through it. From theoretical considerations and drawings and actual experiments the author enunciated the theory that in the lungs on account of the arrangement of the bronchial tree and the natural moisture of the mucosa dust does not penetrate very far. To substantiate this fact there are the observations that in those exposed to dusty air, the vast majority of the dust particles remain in the mouth and in the walls of the larynx. Similarly in the nose when its cavity is normally arranged a very large portion of the dust will be taken up. In spite of all these considerations the author does not deny the fact that dust does occasionally reach the terminal bronchi and the alveoli of the lungs. This he was able to demonstrate in an experimental way and describes the causes as follow. With abundance of dust and an unhealthy, superabundant, rather watery bronchial secretion and with at the same time an excitement of the respiratory function, in such a manner that the inspiratory effort is stronger than the expiratory, it slowly transpires that the dust-laden air charges the secretion, and this is by degrees drawn more and more into the smaller and smaller bronchi until finally the alveoli are reached.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held April 2, 1901.

The President, Joseph Collins, M.D., in the Chair.

Recurrent Oculomotor Palsy.—Dr. William M. Leszynsky presented a woman, twenty-nine years of age, whom he had first seen four months ago. When six years old she had begun to have attacks of headache confined to the right temporal and supraorbital regions, and invariably accompanied by vomiting. The attacks occurred every five or six weeks. At her twelfth year the customary paroxysm had been associated with ptosis of the right eye, from which she had recovered in two weeks, the migraine continuing to recur as before. The second attack of oculomotor paralysis had occurred in her nineteenth year, with the same pain and vomiting. There were partial ptosis, diplopia and inability to look upward with the right eye. She had improved in three weeks, but the eye did not move upward as well as before for a few months and then there had been complete recovery of motility. The third attack had occurred in her twenty-second year, and had been characterized by almost complete ptosis, outward deviation of the eye and diplopia. She had been obliged to keep the eye covered for three months, but had recovered in about a year. The fourth attack had been two and a half years ago and the fifth only three weeks ago. She now complained of the eye turning outward and of her inability to look upward. The periodical headaches bore no relation to menstruation. Examination showed slight drooping of the right upper eyelid, paralysis of the superior rectus and paresis

of the inferior and internal recti. The right pupil is 5 mm. in diameter and rigid, while the left measures 3.5 mm. and reacts normally. Vision is normal in both eyes, and the fields and fundi are normal. She is anemic and neurasthenic. The family history was unimportant, and her ocular condition had practically remained unchanged since the first examination. The speaker said that the most interesting features were the comparative rarity of this type of oculomotor palsy and its pathology. Only two authentic cases of recurrent oculomotor palsy had been studied postmortem, one by Richter, in 1887, and the other by Karplus, in 1895. In the former, a fibrochondroma existed in the course of the nerve trunk at the base of the skull, and separated but did not destroy the nerve fibers. In the other case, there was a neurofibroma of the motor oculi at the base. In many of the reported cases complete recovery had taken place, but in others the paralysis had gradually increased during the intervals, and had ultimately become permanent. Dr. Leszynsky said that he had seen four other cases. In the first, there had been complete paralysis of the third nerve with a clear history of accompanying migraine. Recovery had been spontaneous.

Dr. B. Sachs said that these cases were extremely rare, though he had been fortunate enough to see two in the past six months. One had been in a boy of four years who within a year had had two distinct attacks of oculomotor paralysis of one eye. He had recovered in a few months from the first attack. The family history was entirely negative. He understood that improvement had followed the second attack. There had been apparently no migraine here.

Dr. Leonard Weber said that he had presented a case of this kind to the Society twelve or more years ago. The man had oculomotor palsy on the right side. He had watched the case for a number of years. After about two years there had only been a little ptosis remaining. After a course of iodine the man had greatly improved, and had ultimately died of pulmonary tuberculosis.

Dr. B. Onuf said that he had presented such a case to the Society one year ago. The patient had since been given iodide of potassium in increasing doses, and had moved to the country. The attacks had become shorter and less severe. He did not believe that there was always a lesion of the oculomotor alone. His own case was undoubtedly one of migraine.

Dr. Leszynsky said that a very novel theory had been brought forward regarding this paralysis occurring in connection with migraine. It had been assumed that there is an increased vascularity of the hemisphere during the attack of migraine, causing a disturbance of the function of the third nerve.

Malignant Tumor of the Shoulder Perforating the Spinal Canal.—Dr. Leonard Weber read this report and presented the specimen. The subject was a man of thirty-one whom he had first seen in 1891. He had presented the usual symptoms of a recent syphilis, and had been treated for this with improvement. In 1894 he had returned because of a perichondritis of the cartilaginous portion of the nasal septum. At this time a small movable tumor, the size of a cherry, was noted in the right shoulder. This was supposed to be gummatous. The tumor diminished under mixed treatment, but a small nodule remained. In June, 1900, the man had sought relief because of a hard, solid and almost immovable tumor of the shoulder, which he said had developed shortly after a blow on the shoulder received one year previously. No benefit had resulted from rapidly increasing doses of iodide or from the biniodide of mercury. Three months later a portion of the growth was submitted to microscopical examination, with the result that it was declared by two pathologists to be a round-cell sarcoma. An effort had then been made to remove the growth, but this had been found impracticable. Injections of arsenite of soda and carbolic acid had been given for a time, but without benefit. On December 3d he had been admitted to St. Mark's Hospital because of a suddenly developed paraplegia. Bed-sores soon formed and he became septic, and died on February 11, 1901, from exhaustion. The tumor and a portion of the spinal cord were removed postmortem. The tumor was found to lead into the spinal canal. The cord symptoms in this case were due to hemorrhage and degenerative myelitis. As to whether the little tumor first felt in the shoulder was specific, the speaker said that this was probable, and added that the case emphasized the desirability of removing apparently innocent tumors at an early stage.

Cerebellar Apoplexy with Autopsy.—Dr. Weber also made this report. The patient was a man, twenty-nine years old, living amid the most unsanitary surroundings. The urine had a specific gravity of 1,024, and contained a slight trace of albumin and some hyaline and granular casts. There was no history of syphilis. He had been sick for about two months before coming under observation on September 11th. There was constant headache, but no sensory or motor disturbances. The diagnosis seemed to lie between tumor, hemorrhage and abscess of the cerebellum. On account of the length of time that he had been sick abscess seemed to be more probable than hemorrhage. He died in a few days, and at the autopsy the entire venous system was found engorged with blood. There was marked hypertrophy of the left side of the heart; no endarteritis of the arch of the aorta; both kidneys were slightly enlarged, the cortex showing proliferation of connective tissue in patches and presenting the gross appearance of interstitial nephritis. No opportunity was given for

microscopical examination. In the substance of the right cerebellar hemisphere was an accumulation of both recent and old coagula, and the apoplectic focus had ruptured into the fourth ventricle. He had seen one case of cerebellar apoplexy in a girl of twenty-five years, who had an unsuspected and untreated syphilis.

Tumor of the Optic Thalamus.—Dr. Joseph Fraenkel presented this specimen, which had been taken from a patient whom he had shown to the Society in January, 1898. At that time the boy had had the cardinal symptoms of brain tumor and a paralysis of the face which was very marked when there was any emotional disturbance. There had been no hemianopsia. The boy had been discharged from the Montefiore Home, and had done fairly well for two years and a half. When readmitted, there had been very nearly the same symptoms as before, and in addition a much more marked unsteadiness of gait and a disposition to fall to the right side. Dr. Fraenkel said that he had been led to think it possible that the tumor was after all situated in the cerebellum. On removing the brain at autopsy, a very old cyst was found on the fourth ventricle, the exact nature of which had not yet been determined. There was also a large tumor occupying the right optic thalamus.

Fracture Dislocation of the Cervical Spine.—Dr. Edward D. Fisher reported this case and presented the specimen. The patient was an acrobat, twenty years of age. While turning a somersault from the shoulders of a companion he had fallen a distance of about five feet, and struck on his head. He was instantly paralyzed. When seen by the speaker that evening there had been complete anesthesia from below the nipple extending down the arms to the armpit, and on the inner side of the arm and forearm, and taking in the ring and little fingers. There was complete loss of motion and paralysis of the bladder and rectum. The reflexes, superficial and deep, had been completely lost. Permission could not be obtained for operation until three days later, and in the meantime there had been a temperature range of 104° or 105° F. The operation had had been done by Dr. B. F. Curtis under cocaine anesthesia; and the laminæ of the fifth, sixth and seventh vertabræ removed. No evidence of injury to the cord could be discovered. The man died three days later. The autopsy had revealed a fracture of the body of the seventh vertebra, no subdural hemorrhage, but marked softening of the cord at the seventh cervical segment. There was very little gray matter left in the cord at that level, and there was very little evidence of hemorrhage into the cord proper. A very prominent symptom had been the extreme pain experienced along the course of the nerves. The classical distribution of the paralysis and the complete loss of reflexes were interesting features.

Dr. B. Sachs remarked that twenty years ago it had been pointed out that a very significant symptom of tumor of the optic thalamus was this peculiar facial palsy made visible by emotion.

Dr. Leszynsky said that he had seen recently a case of dislocation in the dorsal region with loss of reflexes and paralysis below the seat of injury. An operation had been done, but death had followed. The autopsy had revealed a complete transverse destruction of the cord.

Dr. Fraenkel said that some time ago he had presented a paper to the Society on this matter of the reflexes, and had continued to give a good deal of attention to this subject. He would assert that the skin reflexes are not lost in total destruction of the cross section of the cord, and the relation of the tendon reflexes to the skin reflexes should enable one to decide whether or not the cord has been completely destroyed in this manner. When the compression of the cord was sufficiently great to interfere functionally with conduction upward and downward, the tendon reflexes are lost while the plantar reflexes are exaggerated. When, however, there is structural disease of the entire cross section of the cord, the plantar reflexes are also lost. This he considered a valuable point in the differential diagnosis. He had reported two cases with autopsies in which there had been loss of reflexes without total abolition of the conduction in the cord.

Dr. Leszynsky said that in the case he had just referred to all forms of reflexes had been abolished, both superficial and deep.

Brain from a Case of Epilepsy Operated Upon.—Dr. H. L. Winter exhibited this specimen, which had been taken from a child of seven years. All of the head measurements were small; there was no paralysis of any of the muscles. The child was imbecile and had epileptoid seizures which appeared to be general. Dr. Stewart had operated upon the child at Bellevue Hospital. On reaching the brain a large cyst cavity had been found in the left hemisphere. The child died seven days later with a high temperature. The hemisphere was found to have been nearly destroyed by the cyst, and the convolutions were not well marked. The interesting feature was the almost complete destruction of the hemisphere without any paralysis. The fibers of the medulla were found not to decussate as freely as usual.

Abscess of the Brain.—Dr. Joseph Collins presented this specimen. It had been impossible to make a localizing diagnosis. The patient was a man, twenty-seven years of age, a tailor by occupation. Two weeks before admission he had been suddenly seized with severe and more or less paroxysmal headache distributed over the whole head. The pain was almost intolerable for six days, and then he became dizzy and had projectile vomiting without nausea. There had been some whistling sound

in the right ear. When seen by the speaker, four days after coming into the hospital, there was double choked disk, but no hemianopsia. There was no leucocytosis, although the hemoglobin percentage was 36. Apparently there was no impairment of hearing. The knee jerks were normal. There was no evidence of palsy or of spasm in any part of the body, and no symptoms referable to the special senses. The patient died four days later of exhaustion. The autopsy revealed an abscess situated in the right hemisphere, and involving particularly the posterior end of the inferior parietal lobe and of the superior parietal lobe. The cuneus itself was partly implicated. The tit-like extremity of the cuneus, it should be noted, was entirely intact on the side of the abscess cavity, and if the optic radiations are not cut across it would not be difficult to explain the absence of hemianopsia. A diagnosis had been made of abscess of the right superior parietal convolution.

Dr. Fisher said that both the superficial and deep reflexes had been absent in his case, and it was because of this that he had inferred that there was complete destruction of the cord. The operation had been undertaken to relieve the intense pain.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held March 21, 1901.

William B. Coley, M.D., Chairman Pro Tem.

The paper of the evening was read by Dr. Charles Schram. Its title was:

Cerebral Apoplexy, Its Relation to Testamentary Capacity.—It will appear in a subsequent issue of the Medical News.

Cerebral Apoplexy and Property Conveyance.—Dr. Reynold W. Wilcox said that he had an experience with regard to cerebral hemorrhage and the exercise of legal intellectual capacity some four or five years ago. The patient, a man of over fifty, was brought into St. Mark's Hospital in a state of coma as the result of cerebral hemorrhage. The right side of the face and the right arm and right leg were paralyzed. There was also aphasia. The patient recovered his speech only sufficiently to give forth alternate volumes of profanity and obscenity. There was a history of previous alcoholism extending over a long time. For eight or ten days after his admission to the hospital the patient's condition remained about the same. Gradually he recovered some motion in his right leg, but practically none in his right arm. His power of speech did not improve. On the eighteenth or nineteenth day after the stroke he was supposed to have executed a bill of sale of his business down on the East Side of New York City to a woman to whom he was not related, but with whom he had been living for some years. On the twenty-fifth day after his stroke the patient became even more violent than usual and had to be removed to Bellevue where he died three days later. At the autopsy a large hemorrhage was found in the brain and the cerebral tissue was found to be badly torn as the result of the violence of the hemorrhage. It was evident that the original hemorrhage had been very severe and that the consequent pressure upon the brain was sufficient seriously to hamper all higher functions.

Legal Decision as to Capacity.—The patient's sister as executrix of his estate took the matter of the bill of sale into court, claiming that the patient had not been capable as far as his mental capacity was concerned of properly executing any such instrument. Dr. Wilcox was asked to testify as expert in the case. As the patient's right hand was paralyzed at the time when he was supposed to have executed his signature, as he understood very little of what was said to him, and even that without much assurance of his mental clarity, and as he was constantly in an excited condition during his stay in the hospital, the only expert opinion possible was that the patient was not legally capable of making the transfer. After consultation on the part of the defendant's counsel, it was decided to withdraw the suit.

Contracts and Wills.—Dr. Charles Schram in closing the discussion said that the courts are much more lenient in their decisions as to testamentary capacity, than as to the mental capacity necessary for making contracts. The evident purpose of the law is to make it as easy as possible for a man to convey his property to the heirs whom he desires to have it. On the other hand, the formalities connected with contracts are surrounded with many technicalities intended to protect the weak-minded from the fraudulent efforts of shrewd friends or enemies.

While motor aphasia is accompanied by least intellectual disturbance, there are other mental conditions which often develop as the result of the lesion causing the motor aphasia. A man may be perfectly dumb, or unable to utter but a few simple words, and yet be perfectly able to understand words when written or to even to show by writing himself that he understands words spoken to him and can convey his thoughts. In these cases, of course, he is perfectly responsible. In a number of cases the courts have decided that wills made under such circumstances are perfectly valid. With regard to the question of contracts, there are not many decisions in this matter. There is no doubt, however, that courts would require more detailed evidence as to the mental capacity of a patient when a contract's validity was in question than when only a will was involved.

The Physician's Duty.—The physician's safeguard in this matter is to have other doc-

tors see the patient and to have a detailed account of his actions carefully written down so that the Court can judge for itself of the testator's or contractor's capacity. Where there is much wealth involved other physicians should be permitted to see the patient independently, and be allowed to form their judgment without knowing the opinion of other experts in the case.

Ascites and Malignant Abdominal Tumors.—Dr. Henry C. Coe said that he has had five or six cases in the last six weeks in which the question of a connection between ascites and malignant tumors, or the development of malignancy in tumors that were previously benign has been one of the elements of diagnosis. He has been accustomed to consider ascites as a rather important symptom, or at least, suspicious sign of malignancy. One of his first cases was a woman of seventy who had suffered from a series of gynecological troubles, most of them connected with an old abdominal tumor. She developed ascites, which became so annoying as to require tapping. Her respiration was so much interfered with that when the ascites began to redevelop, operation was considered. Dr. Coe thought that under the circumstances operation was contra-indicated. He feared to find a rather extensive carcinomatous condition. He refused at first to operate, but was practically forced to do so by the family physician. He found a large adenocystoma of the ovary which he removed and the patient made a good recovery.

Ascites in Benign Tumors.—Dr. Coe's second patient the woman of forty-five, colored, who developed ascites after running down in health and becoming emaciated. The underlying conditions seemed surely to be malignant. On operation a hard tumor of the ovary was found with a number of nodular growths on the intestines. These nodules seemed to be surely secondary malignant growths and the whole picture gave the impression of cancer. Some of the smaller tumors occurred on the periphery of the large tumor making an interesting, knobby picture. The smaller growths proved to be mainly tubercular enlargements of glands and tuberculous nodules.

In a third case an abdominal tumor had been present for fifteen years. Ascites developed rapidly and some evening temperature was noted. The diagnosis was either malignant tumor or a supprating fibrocystoma. The operation showed that the tumor was a fibrocystoma, the contents of which had turned to pus These cases serve to show that it is extremely difficult to decide in any given case whether malignancy is present in the case, or not.

In a fourth patient, aged thirty-six years, ascites had developed about two months before she came under Dr. Coe's observation. This developed rapidly and as a consequence produced marked dyspnea. For this she was tapped several times. The operation showed that she was suffering from double cystoma of the ovaries, the tumors being papillomatous in character. The patient made a good recovery and has continued well ever since.

Significance of Ascites.—Dr. Egbert H. Grandin said in the discussion that the presence of ascites is not necessarily significant of malignancy. When even benignant tumors persist for a long time they often cause the development of copious ascites. Tuberculosis of the peritoneum is usually accompanied by ascites. This is prone to occur in corpulent women, in whom the presence of tuberculosis may not be suspected. As a rule the absence of distinct tumor, taken in connection with ascites, means tuberculosis. Dr. Grandin has seen some cases in which malignant disease of the ovaries finally led to the diagnosis of ascites and this brought the patients to the surgeon. As a rule, however, ascites cannot be spoken of as in any sense pathognomonic of malignancy.

Secondary Carcinoma and Ascites.—Dr. William B. Coley said that the development of a secondary cancer of the intestine, as when, for instance, there is metastases from the breast, often produces ascites. On the other hand, in the cases that have been under his observation, primary cancer of the intestine has not produced ascites. Ascites is more frequently seen with tuberculosis of the peritoneum than with any other condition. The presence of ascites should usually lead the surgeon to suspect the presence of tuberculous glands in the abdomen or even a more extensive tuberculous process.

Mechanism of Ascites.—Dr. George E. Brewer said that ascites is usually caused by the involvement of a gland in some pathological process, which causes it to enlarge and press upon the superior or inferior mesenteric vein. Enlarged glands are usually due to malignant disease or to tuberculosis. The presence of ascites, then, usually indicates either cancer or tuberculosis. In most cases, however, the enlargement of glands is apt to be tubercular.

Teratomata.—Dr. Coley presented specimens of a teratoma of the testicle which had been removed from a patient twenty-seven years old. No enlargement of the testicle was noticed up to eight months before the operation. There was no injury in the history and no tuberculosis in the family. There was no suspicion and no history of syphilis. The tumor grew slowly and gave no pain. At the end of eight months it had grown to the size of an orange. On removal it proved to be a teratoma of the testis, evidently deserving this name, since in it could be demonstrated all three of the germinal layers of the original embryonic tissue—epiblast, hypoblast, and mesoblast. At times, of course, such tumors prove to be malignant. When a number of

such cases are followed, it is surprising how often it will be found that notwithstanding prompt and supposedly complete removal, the tumors recur in the cord higher up, or within the abdomen and cause death.

Theories of Causation.—Various theories have been offered for the explanation of the origin of teratomata. One theory supposes that two ova were originally impregnated and only one developed. The undeveloped one later receives an impulse that causes it to produce a teratomatous growth. A second theory is that by some accident certain cells became split off from the original germ cells before they had developed very far. It is well known that if when the germ contains but two cells, one of them be destroyed an animal will develop complete in all its parts, though the animal is smaller than it would otherwise have been.

Hypothetic Partial Hermaphroditism.—A third hypothesis supposes that partial hermaphroditism exists in these cases and that some of the opposite sex cells included in the genital organs become impregnated and produce the teratomatous growth. Certain large cells have been pointed out as existing in some testicles, which were considered to be primordial ova. Other observers, however, consider these large cells as nothing more than connective tissue corpuscles. This hermapthroditic theory would explain better than any other the fact that most teratomatous tumors develop about the age of puberty. These tumors, however, are known to occur much earlier. They have been reported as early as three and eight months. It is doubtful too if hermaphroditism would be required since the pathogenic impregnation of the ova seems not impossible according to modern observation.

Terminology of Teratoma.—Dr. Frederick R. Sturgis said that there is some confusion as to the application of the term teratomata. This name properly should be applied only to such tumors as contain hair, skin, bones, etc., that is, representatives of all the tissue of the human body. Of late, however, the tendency has been to call all tumors of the testicle or ovary, which contain tissue that may originate from the three original germ layers, teratomata.

With regard to the malignancy of these tumors, Dr. Sturgis considers that many of them seem to become malignant because they were originally secondary malignant tumors, there being other malignant tumors in the body. In a case under his own observation the patient had suffered an injury to his testicle while riding on his bicycle. At the time swelling and pain developed. Later a painless tumor grew. Notwithstanding careful removal of all tissues that seemed to be involved, the patient died from carcinomatous infiltration of the lumbar gland. After his death, a bit of history became known that had not been known before, namely, that he had been injured severely in the abdominal region, some years before the bicycle injury to his testes. It seems probable that the first injury caused the development of an abdominal malignant tumor which gave a metastasis later to the testicle because that organ had lost some of its resistive vitality as the result of injury at the time of the bicycle accident.

Expectation of Life.—Dr. Curtis said that the average length of life after the development of a teratoma is from two to three years. The sooner operation is performed after the general character of the tumor is recognized the longer is the expectation of life. At the best, however, the prognosis is rather hopeless. The custom generally is not to consider these tumors as very malignant. But any one who has followed up a series of cases knows that they almost invariably terminate fatally by post-operative recurrences of true malignant type.

Indications for Operation.—Dr. Eugene Fuller said that it is a good rule to remove anything in the testicular region that develops rapidly. There is always a marked tendency to malignant degeneration in these tissues. To wait for assurance of diagnosis is often to waste valuable time. Where there is not a reasonably good suspicion in the history of syphilis or tuberculosis, even the therapeutic tests for these chronic pathological processes may prove not only futile, but almost fatal to the patient. In one case recently, Dr. Fuller kept a patient for two weeks on the iodide in order to assure himself that the tumor was not a syphiloma. The patient himself insisted that he had not had syphilis. The intra-abdominal glands rapidly became involved and, though the testicle and cord were removed completely, the patient died from recurrence not long after the operation.

Danger of Recurrence.—In closing the discussion Dr. Coley said that with regard to refinements of nomenclature he was not well enough up in the anatomical details of the subject to discuss them. When the three representative tissues of the germinal layers occur in a tumor, there seems to be an agreement among the pathologists that it shall be called a teratoma. Hence the name given to the tumor in the present case. The surgical indication for these cases is removal of the tumor as soon as it is discovered. Even though the malignancy of the removed tumor may be doubtful, one can look for recurrence. Almost inevitably recurrences take place. There seems to be a virulent malignancy about these growths that causes seeds of them to be disseminated widely and at some distance from the original tumor. The removal of the whole tumor, then, becomes in most cases a practical impossibility.

Sarcoma of Testicle.—Dr. Coley has seen

sixteen cases of sarcoma of the testicle, that is, of the tumors he considers primary. In one-half of these there was some antecedent injury in the history. As a rule, there was but a very short interval between the subsidence of the acute traumatic symptoms and the development of the malignant tumor. In the case of the teratoma presented, four weeks after the tongue of a wagon had produced the injury, a round tumor developed. Though it was considered at first to be non-malignant the testicle was removed and with it the cord up to the internal ring. Despite this wide removal of tissue death took place three months later as the result of the development of a tumor in the kidney. Two microscopic examinations of the original tumor removed from the testicle seemed to show that it was not malignant and at most only a granuloma. Repeated examinations aroused the suspicion of round-cell sarcoma. The tumor which developed in the kidney proved to be a round-cell sarcoma.

Bicycle and Malignant Testicular Tumor.—In three of the sixteen cases of primary sarcoma of the testes which Dr. Coley has had under observation the injury which led up to the development of the sarcoma came as the result of bicycling. There is no doubt that acute trauma either serves to arouse dormant connective tissue cells, or else so lowers the resistive vitality as to permit the irritant which causes the tumor to secure a favorable opportunity for lodgment in the tissues. Connection between the injury and the malignant tumor in these cases is undoubted. With regard to the idea advanced by Dr. Curtis that some of the teratomata develop as secondary growths to some malignant tumor within the abdomen, it would seem much more straightforward to consider the testicular tumor primary. The teratomata develop in young and healthy men, who have previously had no abdominal symptoms and they come as the result of direct injury to the testes.

BOOK REVIEWS.

Medico-Surgical Aspects of the Spanish-American War. By Lieut.-Colonel Dr. Nicholas Senn. American Medical Association Press, 1900.

The book is a series of letters written evidently in haste by Dr. Senn from his various posts of duty during the war, and is illustrated with photographs of prominent generals and army surgeons and with views of places.

Most of the letters are made up of rhetorical descriptions of scenes and places, and here and there are to be found instructive comments, such as would naturally be made by a keen medical observer, and there are a number of entries embodying conclusions, which the writer's experiences especially fit him to make, such as those on the "First Aid Packet," the training demanded for an army surgeon, and the surgical operations most frequently necessary for an army corps.

Physical Diagnosis in Obstetrics. By Edward A. Ayres, M.D., Professor of Obstetrics in the New York Polyclinic; Attending Physician to the Mothers' and Babies' Hospital. E. B. Treat & Co., New York.

Dr. Ayres says that his manual of physical diagnosis in obstetrics aims "to represent on paper, and with more careful expansion of statement than could be given in daily verbal instruction by the side of the patient, the clinical study of obstetrics, as the author has been accustomed to pursue it with his classes in hospital and dispensary work." He thus sets himself a very high standard, as his many students will readily recognize. He has not, however, failed to reach his standard. He has made a very practical and useful manual for the practitioner.

The following statement with regard to antepartum examinations is of special interest, because it is often urged that they are infeasible in private practice. By laying stress on such points as determining the time of labor and with many the sex of the child, and the value of forseeing difficulties and thereby avoiding them with the more seriously inclined, it is rare that ready permission is not gained to make antepartum examinations if care is taken to avoid needless exposure.

There are many points in the book that are indicative of Dr. Ayres' very practical methods of teaching.

The Essentials of Practical Bacteriology. An Elementary Laboratory Book for Students and Practitioners. By H. J. Curtis, B.S., M.D. Longmans, Green & Co., London, New York and Bombay.

This is an excellent manual for the laboratory student, and it can be most heartily commended as being small in size, reasonable in price and accurate in statement. While there are plenty of such manuals now published this can be singled out as belonging to the best class of this type of work.

The Nursing Profession. How and Where to Train. By Sir Henry Burdett, K.C.B. Third Year. The Scientific Press, London.

This is a compact and thoroughly reliable guide for the aspirant who desires to take up the vocation of trained nursing. Unfortunately the information bearing on schools in the United States is very meager, the majority of the described training schools being in England, Ireland, Scotland and on the Continent.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, MAY 4, 1901. No. 18.

SPECIAL ARTICLE.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

BY CHARLES W. DULLES, M.D.,

OF PHILADELPHIA;

LECTURER ON THE HISTORY OF MEDICINE, UNIVERSITY OF PENNSYLVANIA.

THE history of the oldest medical school in the United States carries us back to a time when the people of this country still exhibited the punctilious attention to matters of politeness and courtesy which prevailed before the printing press, the steam-engine and the various applications of electricity combined to give this country a peculiar character of haste and strenuous exertion. That was the age of canes and peruques, of formal manners, of respect for authority, and deference to age, of many graceful traits which have almost disappeared in the bustle and hurry of our day.

Before the organization of the Medical Department of the University of Pennsylvania in 1765, the only form of medical instruction in this country was that furnished by individual practitioners to whom were apprenticed such youths as desired to enter upon their calling, and who were sometimes compelled to perform not only the duties of an assistant, in preparing medicines and keeping records, but also those of a drudge in carrying these medicines from house to house and in cleaning up their master's offices and doing other menial services. Of public teaching there had been nothing but a course of lectures in anatomy delivered in Philadelphia by Dr. Thomas Cadwalader about 1750, and another delivered several years later by William Hunter in Newport, R. I., and still later a third given by Dr. William Shippen, Sr., in Philadelphia.

In 1765 John Morgan, a member of the first class that graduated in arts from the College of Philadelphia, in 1757, and who had received his medical education abroad, returned to this country and proposed the addition of a school of medicine to his Alma Mater. His project, which was endorsed by the Proprietary of the Province, Thomas Penn, and by eminent teachers of medicine in England, met with a favorable reception by the Trustees of the College, and a department of medicine was inaugurated by his election May 3, 1765, as Professor of the Theory and Practice of Physic, while on September 23d, of the same year, Dr. William Shippen, Jr., a graduate of the College of New Jersey, who like Morgan had studied medicine abroad, and had there conferred with

MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

Morgan about the foundation of a medical school in Philadelphia, was made Professor of Anatomy, Surgery and Midwifery.

At the same time Dr. Thomas Bond delivered a regular course of lectures in the Pennsylvania Hospital, attendance upon which was made obligatory upon the students, part of the requirements for the Degree of Bachelor of Medicine, established by vote of the trustees July 27, 1767, being that the applicant should attend one course of "Clinical Lectures," and the "Practice of the Pennsylvania Hospital for one year." This was in addition to furnishing evidence of a good classical and scientific education and attendance on lectures on chemistry in the College.

In January, 1768, the medical faculty was enlarged by the addition to it of Dr. Adam Kuhn, as Professor of Materia Medica and Botany, and in July, 1769, Dr. Benjamin Rush was appointed Professor of Chemistry. Thus the Faculty was made up of men of the highest type of citizens, as men of science and as teachers, each one of whom left an indelible impress upon the development of medical teaching in this country.

At that time, and for long afterward, Philadelphia was the undisputed center of education in America, and Philadelphia physicians and surgeons surpassed those of the rest of the country in number and attainments and reputation. In this, the medical profession in Philadelphia was only keeping step with the other departments of art, science, and industry, for here were established the first medical school, the first hospital, and the first dispensary in America, the first fire company, the first circulating library, the first company for insurance against fire, the first local periodical, and the first bank; while in Colonial times and long afterward Philadelphia was the center of study for botany, astronomy, natural history, and all the sciences that were pursued at that age. Philadelphia also furnished the material to form the American Philosophical Society, which for many years was to our country very much what the French Academy has been to France—the focus of learning of every sort. The College of Philadelphia (afterwards the University of Pennsylvania) enjoyed the public recognition of the highest officials of the British Government before the War of the Revolution, and to its halls were gathered, from all parts of the country and even from foreign lands, students who sat at the feet of teachers who were the honored and equal colleagues of the most eminent scientific men of Europe—the often-quoted sneer of Sidney Smith in regard to American achievements in science and art being founded upon his ignorance as much as upon his spleen.

It is hard now to picture to ourselves the conditions which existed in Philadelphia at the end of the eighteenth century: the strip of houses along the Delaware, the smallness of those houses, the unlighted streets, the want of public conveyances, the watchmen stalking sleepily through the town at night, and greeting from time to time the doctor, wrapped in his cloak and supported by his cane, as he went on his errands of mercy, and to realize the state of the country at a time when its only original work on surgery was that of John Jones of Philadelphia, entitled: "Plain, Concise and Practical Remarks on the Treatment of Wounds and Fractures"—a little book put out in 1776 for the use of surgeons in the armies of the Colonies—and when Shippen's house was attacked by what is known in history as the "Sailors' Mob," and he was compelled to deny in print the accusations of grave-robbing.

The general standing of the College of Philadelphia at this time may be inferred from the fact that in 1763 its students numbered nearly four hundred and were gathered from different parts of the Colonies as well as from the West Indies and other adjacent provinces and islands. The establishment of the department of medicine was the occasion for the expression by Dr. Morgan of the following hope which was abundantly fulfilled when it became not only the special glory of the University, but also the greatest school of medicine in the country: "Perhaps this Medical Institution, the first of its kind in America, though small in the beginning, may receive a constant increase of strength, and annually exert new vigor. It may collect a number of young persons, of more than ordinary abilities, and so improve their knowledge as to spread its reputation to distant parts. By sending these abroad duly qualified, or by exciting an emulation amongst men of parts and literature, it may give birth to other useful institutions of a similar nature, or occasional rise, by its example, to numerous societies of different kinds, calculated to spread the light of knowledge through the whole American Continent, wherever inhabited."

The outbreak of the war between the Colonies and the mother country seriously interrupted the course of teaching in the College of Philadelphia, partly because fewer persons presented themselves to be taught—so many having joined the army—and partly because the teachers of the institution themselves took an active part in the struggle and gave their services to their country: all of the four professors who began the work of teaching—Morgan, Shippen and Rush—being attached to the Continental Army as medical officers. In the year 1779 the party in power in the new State of Pennsylvania, for reasons which cannot now be either understood or justified, passed an Act annulling the charter of the College of Philadelphia and organized an institution to which was given the name of "The University of the State of Pennsylvania." This act of injustice did not

destroy the vitality of the College or secure prosperity for its intended supplanter; and in 1789 the Legislature restored the rights of the College of Philadelphia and declared its previous action to have been "repugnant to justice and a violation of the Constitution of this Commonwealth and dangerous in every precedent to all incorporated bodies." Two years after this the institution which had been meant to supplant the College of Philadelphia proposed to merge its existence in that of its predecessor and on September 30, 1791, the two were united by the Legislature and made into one institution to be carried forward under the title of the "University of Pennsylvania."

When the struggle of the Revolution was ended and the work of organizing and solidifying the affairs of the Colonies was progressing, the Faculty the teaching of anatomy was freed from the burden of instruction in surgery and in midwifery, the latter of which was generally regarded as rather demeaning to a medical man, and all three branches were endowed with greater dignity. It is a curious indication of the sentiment of the time that when James was appointed Professor of Midwifery, the Trustees provided that it was not necessary, in order to obtain a degree, that the students should attend his lectures. In 1813, however, the Chair of Midwifery was placed on an equal footing with the other Chairs of the Faculty.

Of its first teachers, posterity has preserved the liveliest recollection. John Morgan, who shared with Shippen the glory of having founded the Department of Medicine, conducted the duties of his Chair until his patriot-

UNIVERSITY, COLLEGE AND MEDICAL HALLS.

the Medical Department of the University of Pennsylvania increased in scope, so that in 1792 its Faculty consisted of William Shippen, Jr., Professor of Anatomy, Surgery and Midwifery, with Caspar Wistar as Adjunct; Adam Kuhn, Professor of the Theory and Practice of Medicine; Benjamin Rush, Professor of the Institutes of Medicine and Clinical Medicine; James Hutchinson, Professor of Chemistry; Samuel P. Griffitts, Professor of Materia Medica and Pharmacy; and Benjamin Smith Barton, Professor of Botany and Natural History. The year 1805 was remarkable in the history of the University by the establishment of a separate chair for the teaching of surgery, to which was appointed Dr. Philip Syng Physick, while in 1810 Thomas Chalkley James was made Professor of Midwifery. By these two additions to

ism led him, with many of his colleagues, to place his skill at the service of his country. At the end of the Revolutionary War he did not return to his professorial position on account of failing health.

More happy in his career, Shippen was for over forty years a professor in the University, teaching at first the then allied subjects of anatomy, surgery and midwifery—which in that day was a department of surgery—and concluding as Professor of Anatomy when this branch was considered worthy of the best efforts of a single teacher. Shippen did more than any other man in this country to induce a proper consideration for the subject of midwifery. As early as 1765 he had established a course of private lectures in which he proposed "to instruct those women who have virtue

enough to own their ignorance and apply for instruction, as well as those young gentlemen now engaged in the study of that useful and necessary branch of surgery, who are taking pains to qualify themselves to practise in different parts of the country, with safety and advantage to their fellow citizens." His career as an anatomist, however, overshadowed his other worthy achievements. He combined great ability as an anatomist with a singularly pleasing and successful method of instruction, so that those of his pupils who had studied abroad declared that they had met no man superior as a demonstrator of anatomy and very few indeed who were his equals.

It is hard to think of the name of Benjamin Rush without recalling the majestic figure he became, or to fancy him a graduate of the College of New Jersey at the age of sixteen years, a student in the office of the eminent Dr. Redman of Philadelphia, and returning from studies in Edinburgh, where he received the degree of Doctor of Medicine, to occupy when only twenty-four years old the Chair of Chemistry in the College of Philadelphia—the first Chair of Chemistry established in North America. He brought with him the endorsement of Thomas Penn, who wrote that Dr. Rush had been recommended to him by Dr. Fothergill as a "very expert Chymist" and added "the Doctor having further recommended to me to send a Chymical Apparatus to the College, as a Thing that will be of great use, particularly in the tryal of ores, I send you such as Dr. Fothergill thought necessary, under the care of Dr. Rush, which I desire your acceptance of." Youngest of the members of the Faculty, whose ages ranged from twenty-four to thirty-four years, Rush became the greatest of them all, adding to a position as a teacher, which has led to his being called the Galen of America, extraordinary services as a public man, as surgeon-general to the Continental Armies, as Member of Congress and as a signer of the Declaration of Independence. So wide did his fame extend that in 1811 the Emperor of Russia sent him a diamond ring as a testimonial of respect, while in this country he was so great that no man of his time or since can be compared with him as a medical teacher. Indeed, in our day it is hard to understand those days in which a man was so much a master of his followers. And yet he did not escape detraction, for one of his enemies, taking the sobriquet of "Peter Porcupine," issued, from the security of New York, a periodical which he named the "Rush Light," devoted solely to bitter abuse of him.

James Hutchinson, a graduate in arts of the College of Philadelphia, took his degree of Bachelor of Medicine there in 1774. His tickets to the lectures of the Professors of the College, which are still in the possession of his descendants, were written upon the backs of playing cards. After studying in England he returned to America by way of France bearing important dispatches from Franklin to the Congress of the United States. When near the American coast the ship in which he was a passenger was chased by a British armed vessel and, to save the dispatches, he left the ship and in an open boat under a heavy fire succeeded in landing with his precious documents intact. The ship was soon captured and he lost everything he had on it, including a fine medical library collected in England and in France. To this service to his country he added the evidence of patriotism then usual in the medical profession, that he served in the Continental Army as a medical officer and as a volunteer, and afterwards in the State Navy, for the handsome remuneration of at first three shillings per day and finally for the magnificent sum of three or four pence.

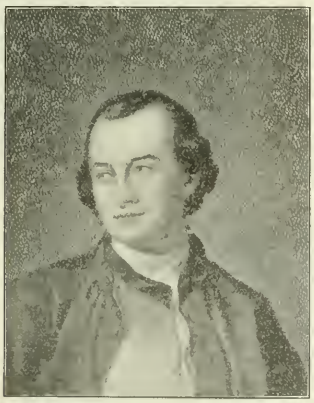
Samuel Powell Griffitts, who lectured only six sessions and then resigned, was largely influential in the establishment of the Philadelphia Dispensary in 1786, and interested in the formation of a National Pharmacopœia, projected in 1778 by the College of Physicians of Philadelphia and finally brought to accomplishment in 1820.

Benjamin Smith Barton was the pioneer of the science of botany in America, not only distinguished himself, but also followed by a number of distinguished disciples. In teaching he had the advantage of being skilful with his pencil in illustrating his subject—an art which he acquired under the instruction of Major André, when he was a prisoner of war at Lancaster where Barton was born.

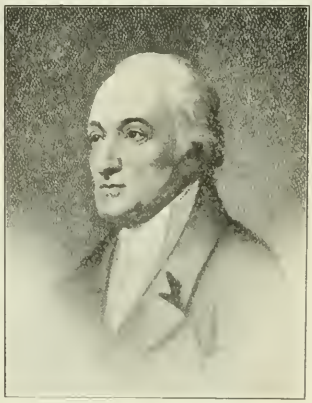
Caspar Wistar was one of the most attractive and influential men of his period. He was a disciple of John Redman and John Jones—then practising surgery in Philadelphia—a graduate in medicine of the University of the State of Pennsylvania and trained abroad. He taught first chemistry and then anatomy in the reinstated College of Philadelphia. He had rare skill as a teacher and was singularly inventive in methods of demonstration to the students, and in preparing specimens and models which are still used. His anatomical preparations, presented to the University by his widow, supplemented in 1824 by the anatomical collection of the Pennsylvania Hospital which was given by the Managers to the University, and at a later date by the preparations of Dr. Horner, constituted what was for nearly a century known as the Wistar and Horner Museum and was the scientific foundation of the present Wistar Institute of Anatomy and Biology, which is now such an important department in the University.

Thomas Chalkley James, the first actual professor of obstetrics in this country, was one of the earliest graduates in medicine from the college in which he afterward became a teacher. During his studies abroad he was associated with Physick, afterward his colleague

in the University. As a young man, in 1794, he joined those who lent their aid to Washington in suppressing a disturbance known in history as the "Whiskey Insurrection," which at that time seriously threatened the existence and stability of the newly formed republic. He joined the expedition as surgeon of a *corps d'élite*, which promptly tendered its services at the request of the President. As these volunteer troops marched before Washington on their way to the scene of the conflict, he was heard to say with emotion: "God bless you! God bless you, young gentlemen!" James was largely influential in having established at the Philadelphia Alms-House, in 1802, a lying-in ward, to which he was the first accoucheur; he was also, in 1810, made the first "Physician to the Lying-in Department" in the Pennsylvania Hospital, part of the funds for the establishment of which were contributed in 1807 by the gallant and patriotic young gentlemen of Philadelphia who constituted the "First Troop of City Cavalry," an organization still in existence and enjoying the prerogative of being body-guard to the President of the United States whenever he visits this State. The members of the Troop gave to the Hospital the entire amount of their pay—long withheld—for services rendered their country during the Revolutionary War, and the interest on this sum amounted annually to between four and five hundred dollars.



JOHN MORGAN.



WILLIAM SHIPPEN, JR.

Of the men who during the nineteenth century taught in the halls of the University and added to its luster, one of the most conspicuous was Philip Syng Physick, who by his combination of talents and integrity well merited the title of "Father of American Surgery." While studying in Great Britain he was a favorite pupil of John Hunter, who, in his Treatise upon the Blood, awards to Physick the credit of many of the experiments therein described. He received the degree of Doctor of Medicine at Edinburgh in 1792: this occurrence being the occasion of a mark of singular appreciation by the University of Edinburgh to the standing of the University of the State of Pennsylvania in which he had received his medical training under Dr. Kuhn and his colleagues. As surgeon to the Pennsylvania Hospital he delivered private lectures on surgery as early as 1800, and in 1810 he was elected by the University of Pennsylvania to fill the Chair of Surgery which was then first separated from that of Anatomy. Physick's achievements as a surgeon and as a teacher fill a large part of the history of his day. He enjoyed the acquaintance and confidence of the most distinguished men of his time and one of his last operations was a successful lithotomy upon Chief Justice Marshall, then in his seventy-fifth year.

The perpetuation of Physick's reputation depends largely upon the recollections of his pupils and especially of his nephew, John Syng Dorsey, who founded much of the teaching of his Treatise on Surgery upon the practice of Physick. Dorsey was made adjunct Professor of Surgery when only twenty-four years old and soon after a surgeon to the Pennsylvania Hospital. His intimate association with Physick furnished an opportunity of which his genius enabled him to make good use, so that in 1813 he published his Elements of Surgery, which was the first work on general surgery issued in this country and for a long time the only text-book on surgery used in American schools. His death took place in 1818 when he was only thirty-five years of age, within a week after he had delivered his opening lecture as Professor of Anatomy, and brought to

an end a career which in its promise and untimely end suggests that of Bichat. A short time before his death Dorsey removed to a newly built house on the southwest corner of Seventh and Walnut streets, which overlooked what is now known as Washington Square and was then the Potter's Field. On the eastern side of this field was the city

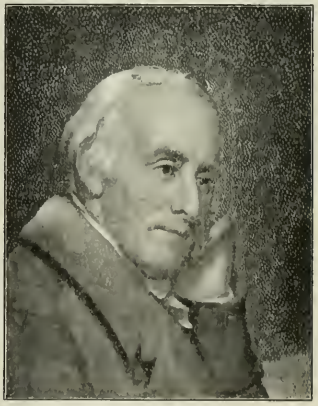
ANATOMICAL HALL IN 1770.

prison, referred to in the annals of that day. He had been in the house but a few days when Judge Peters, an old and intimate friend, called to pay his respects. Standing at the window overlooking the Square, with the prison full in sight, he said: "Dorsey, I do not like your situation; you have a poor prospect before the grave." Another humorous saying connected with the life of Dorsey is attributed to Nathaniel Chapman, who, in reply to some expression of gratification by Dorsey on his appointment as Professor of Anatomy, and the remark that he hoped he would have an opportunity to distinguish himself, said: "Why you are already distinguished, a muscle has been named for you—the *latissimus dorsi*."

During the remainder of the nineteenth century the roll of Professors in the Medical Department of the University of Pennsylvania included the names of the brilliant and versatile Nathaniel Chapman, who after assisting Professor James in the teaching of midwifery was Professor of Materia Medica and then for thirty-four years Professor of the Theory and Practice of Medicine, whose remarkable witticisms served perhaps as much as his ability as practitioner and as a teacher to keep his memory green for generations; of George B. Wood, fifteen years Professor of Materia Medica and ten years Professor of Practice, teacher, trustee, historian and benefactor; of Alfred Stillé, who filled the Chair of Practice from 1864 to 1884, of world-wide reputation as a teacher and author and a man of the highest type of scholarship and refinement.

Stillé's successor in the Chair of Practice was William Pepper, Jr., whose extraordinary talents and unwearied perseverance, in that chair and in the office of Provost of the University, enabled him to greatly expand the field of its usefulness, whose capabilities were Napoleonic, and whom no obstacle sufficed to deter from pursuing to its end any work that he undertook. Toward the end of his life his administrative ability was more conspicuous than his achievements in the line of his profession, but no one who knew him well is at a loss to understand why he occupied so conspicuous a position before the medical profession or before the world.

In the teaching of surgery and anatomy the most memorable names were those of William Gibson, William E. Horner, Joseph Leidy and D. Hayes Agnew. Gibson, who left the Chair of Surgery in the University of Maryland and occupied the corresponding one in the University of Pennsylvania for thirty-six years, is best known by his work on Surgery, which passed through many editions, and the fact that he twice successfully performed Cesarean section upon the same patient. Horner, coming from Virginia, was assistant to Physick and afterward to Dorsey, then, in 1820, Adjunct Professor of Anatomy, and at the resignation of Physick, Professor—a careful, studious and painstaking teacher and an able surgeon, author of a work on Anatomy and contributor of so many specimens to the Museum founded by Wistar that by order of the

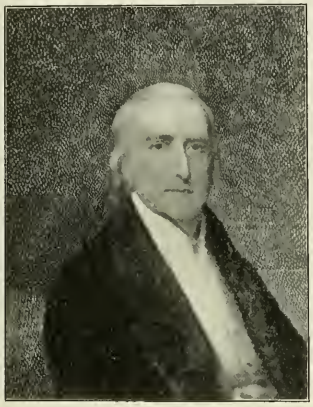


BENJAMIN RUSH.

Trustees it was known after his death as the Wistar and Horner Museum.

Next after Gibson, Henry H. Smith filled the Chair of Surgery for fourteen years, being followed by D. Hayes Agnew, who occupied it from 1871 to 1889—one of the most loved teachers in the Faculty and a surgeon of extraordinary judgment and skill, on whose

words the Nation hung during the weary months in 1881 when President Garfield languished to death from the bullet of an assassin. Though he published a work on Surgery that filled three large volumes, his most lasting monument is the magnificent D. Hayes Agnew Pavilion of the University Hospital, erected by his friends and pupils in his memory. And last—before the present incumbent



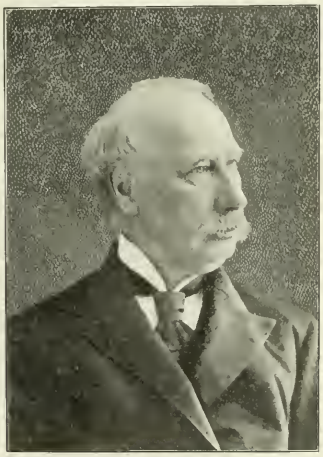
PHILIP SYNG PHYSICK.

—came John Ashhurst, jr., patient, unswerving in integrity, strict with himself, as with others, a fine example of the learned surgeon, leaving the stage just as it came to be filled with those who in their wonder at the achievements of modern surgery have had their gaze averted too much from the wonders achieved by the surgeons of earlier days.

Joseph Leidy, first connected with the University as Horner's Assistant and elected his successor in 1853, was for more than forty years Professor of Anatomy. Though one of the most distinguished naturalists in the world; he was a man of singular modesty and retiring disposition. His lectures were simple and unadorned, save for a faint touch of humor here and there, which was the more appreciated because of its contrast to his habit, and occasionally a passing reference to some minute investigation to which he alluded as though it had not deserved the applause of the scientific world. In the class-room he seemed to know nothing but his subject, and in the "green-room"—as the examination-room was then still called—which in those days tried the soul of the aspirant for a degree, he pushed the investigation of the students' knowledge with as calm an indifference as marked his scientific investigations. They never thought him unkind, though one of his amusements was never to let his victim go without having asked a question which he could not answer.

In the branch of Obstetrics the most conspicuous names were those of William P. Dewees and Hugh L. Hodge. Dewees was best known as the author of several works: one of them being on midwifery and another on diseases of children. The former was—after that of John Bard of New York—the first systematic work on this subject published in this country. Hodge was Professor of Obstetrics from 1835 to 1863 and the author of a work for many years indispensable to the student of midwifery, while he was the designer of a pessary which will probably always be employed in gynecology, and of the form of forceps well known by his name.

The successor of Hodge, in 1863, was R. A. F. Penrose, of whom—as happily he still lives, sole survivor of the Faculty of twenty-five years ago, from which he resigned in 1888—it is not an easy thing to speak. But those who enjoyed his teaching will surely never forget his instructive lectures or the rare treat they had once a year, when, with all the airs of secrecy—doors closed and tickets demanded—they looked down upon the table upon which lay, covered with a decent sheet, the form of Mrs. O'Flaherty, whose wooden frame and chamois-skin integument for so many successive years furnished an example of labor and the opportunty to demonstrate an ac-



D. HAYES AGNEW.

couchment; nor will they forget his humorous stories which fixed in their recipient minds truths which would have found a less cordial welcome if less entertainingly communicated.

Allied with the Department of Obstetrics is that of Gynecology, of which Dr. William Goodell was one of the first and most distinguished teachers in this country. To his success as an operator he added a most pleas-

ing method of lecturing: rare choice in the words used, simple, direct, homely, but singularly attractive. Withal he had the charm of candidly telling of his failures and making them quite as instructive to his students as were his successes.

Then there was Joseph Carson—"old Uncle Joe," he was called—with whose amiability his hearers sometimes took slight liberties, but for whom they all felt the deepest regard and respect; for twenty-six years he taught Materia Medica and Therapeutics with a wealth of knowledge and a depth of thinking that those who learned of him can never forget. Those were the days before manufacturing pharmacists had destroyed the poetry of materia medica; when the old man exhibited his specimens each one of which had for him a living interest like the gourd of "squirting-cucumber" which was always described as having been "sent to me from Joppa by my young friend, Mr. ——, of the United States Navy." Those who listened to him will never forget the tears he could not restrain when he mentioned "my lamented predecessor in this chair, the late Dr. George B. Wood," or the break in his voice when he described the untimely death of the Princess Charlotte, or told of the heart-break of Condamine when his laboriously collected specimens of cinchona went to the bottom of the Amazon just as he was about to enter the ship that was to take him to France. Besides the memories that cluster round his years of teaching he left to the Alumni a History of the Medical Department of the University of Pennsylvania that will perpetuate both its fame and his.

Finally, there was Robert E. Rogers, made Professor of Chemistry after his brother James in 1852, and Francis Gurney Smith, made Professor of the Institutes of Medicine in 1863. Of these Rogers served longest. His lectures were full of interest, and those who attended them can picture him still with his pointer tucked under the stump of his right arm—injured by an explosion years before—while with his left hand he wrote upon the blackboard or manipulated the ingredients of an experiment. Amiable, impulsive, he made chemistry one of the most interesting branches of the curriculum. And Francis Gurney Smith, the polished teacher of physiology—before machinery and vivisection had ruined its graceful proportions or turned their prosaic searchlights into those dim corners where were supposed to lie hid such uncomprehended forces as "catalytic action"—strove not only to lead his hearers to a comprehension of the facts then known in regard to physiology, but also to direct their thoughts to the nobility of their calling, concluding his course of lectures with such pious wishes for their eternal happiness as in this day would hardly fit the general mood of man. And last, Wormley, the rigid, rugged, absolutely unswerving; the man of science—one might say exclusively—the master of his department and seeming to have been made for it.

These are the great men of the past whose mantle now rests on shoulders no younger than were theirs when they began their career—on shoulders which, it is hoped, will grow to such proportions as become the followers of their great predecessors; so that he who describes their generation may feel for them such emotions as we feel toward those who have passed on before them.

The great men of the past are distinguished partly because they produced such results with such meager facilities for investigation and teaching. They had no instruments of precision, some of them had no knowledge of physical diagnosis, and others witnessed its birth. Equally meager were their physical accommodations. The first steps in medical teaching in the College of Philadelphia were taken in the homely old building called "Anatomical Hall," "Surgeons' Hall," on Fifth Street just south of the building still occupied by the Philadelphia Dispensary. Thence the College and the Medical School were removed to Ninth Street, to the building known as the "President's House," erected during the life of Washington and intended as a gift from the State of Pennsylvania to the President of the United States, whose occupancy was declined by President Adams for what he considered constitutional reasons and which was bought in 1800, and first occupied by the schools of the University (except for the chairs of Anatomy and Chemistry) in 1802. In 1829 this building was taken down, and on its site two others were erected which were the home of the University until it was removed to West Philadelphia, where step by step its accommodations increased until they are now probably unequaled in the world. Here is one of the finest dormitories in the country, a wonderful development of the idea which had its first expression in the small building erected in 1762 at the corner of Fourth and Mulberry (now Arch) Streets, with funds raised by a lottery. Here is the first and finest club-house—Houston Hall—ever erected for the use of students, and laboratories for every line of investigation connected with the science and art of medicine, and the Hospital of the University with its 285 beds. The staff of teachers in the Department of Medicine now numbers ninety-seven, and there is no new want discovered that does not receive the prompt attention of the Faculty, of the Trustees, and of the untiring Provost. An early champion for the highest standards of medical education, it is one of the best boasts of the Department of Medicine in the University of Pennsylvania that it stands to-day an acknowledged leader in this respect, and that it bears its full share in upholding the motto of the University, *"Literæ sine moribus vanæ."*

ORIGINAL ARTICLES.

A REPORT OF TWENTY-FOUR OPERATIONS PERFORMED DURING SPINAL ANALGESIA.

BY WILLIAM SEAMAN BAINBRIDGE, A.M., M.D.,

OF NEW YORK;

ATTENDING SURGEON TO RANDALL'S ISLAND HOSPITAL.

The position that spinal puncture is to occupy in the surgical world continues to be an open question. Notwithstanding the favorable reports of many observers and the discouraging experiences of the few, the vast majority of the medical profession are wisely deferring judgment until further experimental evidence has accumulated and any possible remote effects have had time to develop.

The purpose of the present paper is to record the facts concerning some of the actual cases which have occurred in my practice, rather than the giving of an expression to any individual opinion.

In the *Medical Record* of December 15, 1900, I reported my first cases. Since then I have had over forty additional ones and of these the following are selected as of the most interest:

Case I.—J. R., male, aged eleven years; admitted to the hospital with a history of several epileptic attacks. During the past two weeks, no evidence of epilepsy, but distinct symptoms of chronic appendicitis. The last three days has had increased pain at times in the right iliac fossa, with a slight temperature. Cocaine analgesia, February 18, 1901. Place of puncture, to the right between the third and fourth lumbar vertebræ. Amount of cocaine, twenty minims of a two-per-cent. solution. Analgesia to the level of the diaphragm in five minutes after the injection. Vomited five minutes later. At this time it was learned that the patient had by some error secured solid food, although on a fluid diet, and, as far as the stomach was concerned, was totally unprepared for the operation. After this initial vomiting, which lasted but for a moment, there was no nausea or emesis throughout the operation. The usual "gridiron" appendicectomy was performed. The appendix was bound down by adhesions behind and to the pelvic side of the cecum. The peritoneum in the neighborhood of the vermiform, as well as the appendix itself, was acutely inflamed. (Subsequent pathological report on the examination of the appendix confirmed the diagnosis of chronic appendicitis with acute exacerbation.) The operation lasted fifty minutes, and was unaccompanied by pain or discomfort. At the end of the operation the analgesia was still complete to the level of the diaphragm. Before operation, temperature, 99.8° F.; pulse, 92; respiration, 22. Two hours after operation, temperature, 99° F.; pulse, 96; respiration, 24. Analgesia entirely disappeared in two hours and fifteen minutes after the completion of the injection. Slight nausea at one time during the night. Temperature reached 101° F.; pulse, 104; respiration, 26.

February 19th: Twice to-day has seemed to be on the verge of an epileptic attack, clinching the fists and closing the eyes for a few moments. February 20th: Quiet day. No pain. Doing very well. February 26th: Stitches removed. Wound healed *per primam*. Convalescence uneventful. March 11th: Patient allowed to be up. Seems perfectly well. March 16th: Patient continues perfectly well. Discharged cured. No evidences of epilepsy during his stay in the hospital except those already noted.

Case II.—S. A., female, aged fourteen years; a highly neurotic child, large for her age, showing the general signs of malnutrition which so frequently accompany advanced tuberculous disease. Marked tuberculous arthritis of the left knee-joint and considerable contracture of the flexor tendons. Before admission to the hospital, treatment by retentive apparatus proved of no avail. Nocturnal pain materially interfered with sleep and the general health steadily failed. An arthrectomy seemed indicated. Cocaine analgesia, December 21, 1900. Place of puncture, to the left between the fourth and fifth lumbar vertebræ. No difficulty was experienced in introducing the instrument, but the cerebrospinal fluid did not flow and careful examination showed that the needle, although patulous when introduced, had become partially occluded by a small blood-clot. (*a*) A puncture was now made to the right between the same vertebræ and fluid readily flowed from the needle. Amount of cocaine, sixteen minims of a one-per-cent. solution. In seven minutes analgesia was complete to the knees but insufficient for the operation. No nausea or vomiting. (*b*) Second injection between the third and fourth lumbar vertebræ. Amount of cocaine, fifteen minims of a one-per-cent. solution. Analgesia in ten minutes complete up to the level of the clavicles, both in front and behind, including the axillæ. No nausea or vomiting. Operation lasted forty-five minutes, and consisted of an excision of the knee-joint. There was extensive disease involving, not only the bones, but the soft tissues about the joint. After the capsule had been practically removed, ninety-five-per-cent. carbolic acid, immediately followed by strong alcohol, was applied. The patient throughout did not suffer the slightest pain, although at first she evinced some fear. Before operation, temperature, 98.2° F.; pulse, 102; respiration, 24. Two and one-half hours after, temperature, 98.8° F.; pulse, 112; respiration, 36. One and one-half hours after operation was completed analgesia had entirely disappeared. Patient had no nausea or vomiting until two and three-quarter hours after the operation when a repeated request for milk was granted and emesis occurred for the first and only time. Headache during afternoon and evening controlled by small doses of acetanilid, caffeine and sodium bicarbonate.

December 22d: Fair night. Very nervous at

times. Medicine required again for headache. Stomach retentive. Highest temperature, 102° F.; pulse, 128; respiration, 26. December 23d: Patient comfortable. December 24th: Better than before operation. December 25th: Temperature, pulse and respiration normal. Sleeping and eating well.

Case III.—Same patient; general conditions greatly improved. Cocaine analgesia, January 4, 1901. Place of puncture, to the right between the fifth lumbar and the first sacral vertebræ. Amount of cocaine, ten minims of a two-per-cent. solution. Analgesia to the level of the trochanter major in four and one-half minutes. Splint and stitches removed. Parts in excellent condition. Dressed and reapplied splint. Operation lasted thirty minutes, and analgesia entirely disappeared in one hour thereafter. Before operation, temperature, 98.2° F.; pulse, 102; respiration, 24. One and one-half hours after operation, temperature, 98.8° F.; pulse, 120; respiration, 24. There was no nausea or vomiting at any time, and three hours after the operation the patient consumed and retained bread and milk. But for a very slight headache of short duration, patient felt perfectly well.

January 5th: Patient has slept all night. No effects from the cocaine. Highest temperature 99° F.; pulse, 96; respiration, 24. February 14: Up and about, feeling very well, gaining steadily. March 1st: Has gained markedly in flesh and strength. Feels strong and well. Firm union. Splint continued. March 18th: Parents desire patient at home. Light splint applied. Discharged cured.

Case IV.—J. B., male, aged nineteen years. Strong and healthy with the exception of left lower extremity, which is partially paralyzed. Left dropfoot with congenital deformity of both feet. Cocaine analgesia, December 8, 1900. Place of puncture, between the fourth and fifth lumbar vertebræ. Amount of cocaine, twenty-five minims of a two-per-cent. solution. Analgesia to level of diaphragm in five minutes. Operation lasted fifty-eight minutes, and consisted of a tenotomy of the left tendo Achillis with an excision of the ankle-joint on the same side. Patient suffered no pain whatever. Vomiting and nausea were absent, and the only feeling of discomfort was felt a few moments after the injection, and described as "a dull heavy feeling in the stomach." Before operation, temperature, 98° F.; pulse, 74; respiration, 20. The highest respiration during the operation was 30, and the most rapid pulse 130. For some hours the patient complained of severe headache, which required frequent doses of acetanilid, caffeine and sodium bicarbonate before relief could be obtained.

December 9th: Had a fair night. December 13th: Plaster a little too tight. Splint removed; no after-effects from the cocaine.

Case V.—Same patient. Condition excellent but the necessity for further correcting the position of the foot renders some means for dulling pain advisable. Cocaine analgesia, December 22, 1900. Place of puncture, between the fifth lumbar and the first sacral vertebræ. Amount of cocaine, twelve minims of a two-per-cent. solution. Analgesia began in two minutes and extended to the level of the knees in five minutes. Operation lasted about forty minutes, and consisted in the dressing of the ankle and forcibly bringing the parts into a more normal position. There was no pain or discomfort during the operation; no nausea or vomiting. Before operation, temperature, 99° F.; pulse, 94; respiration, 20. One hour after operation, temperature, 99° F.; pulse, 100; respiration, 22. At the close of the operation the analgesia was to the level of the diaphragm and totally disappeared in one hour and fifty minutes. During the afternoon some headache, slight nausea for a few moments, but no vomiting.

December 23d: Had a good night; patient comfortable, except for an occasional shooting pain in the ankle. December 24th: No after-effects of any kind apparent from the cocaine. January 15th: Patient in good condition; convalescence uninterrupted.

Case VI.—Same patient. Condition good. Further operation on the left ankle necessary for best possible result. Cocaine analgesia, January 21, 1901. Place of puncture, between the fourth and fifth lumbar vertebræ. Amount of cocaine, eight minims of a two-per-cent. solution. Analgesia to the level of the hips in ten minutes from the time of the injection. Operation lasted twenty minutes, and consisted of a tenotomy and osteotomy in the ankle and foot. Plaster applied. No nausea, vomiting or discomfort of any kind; patient talked to the physician and commented upon the various steps of the operation. At its completion the analgesia was up to the level of the diaphragm, but disappeared completely in fifty minutes. Four hours after the operation complained of some headache and of chilly sensations. Heat externally gave relief.

January 21st: Feeling very well. January 22d: No after-effects. February 8th: Up and about the ward with crutches. March 28: Convalescence has been uneventful.

Case VII.— J. H., male, aged fifteen and one-half years. Very poor general condition, with marked nephritis. Urine contains albumin, hyaline and epithelial casts; bacillus coli communis abundant. Caries of the ilium and tuberculous hip-joint with several sinuses. Cocaine analgesia, January 15, 1901. Place of puncture, between the fifth lumbar and first sacral vertebræ. (*a*) Amount of cocaine, ten minims of a two-per-cent. solution. Analgesia in ten minutes to the level of the trochanter major. Area of analgesia insufficient for the operation. (*b*) Second injection between the fourth and fifth lumbar vertebræ. Amount of cocaine, seven minims of a two-per-cent. solution. After fifteen minutes from the time of the second injection the analgesia had extended to the level of the free border of the ribs and was complete for the soft

tissues, but some pain was elicited when the bone was attacked. (c) Third injection between the third and fourth lumbar vertebræ. Amount of cocaine, seven minims of a two-per-cent. solution. A few minutes after the last injection the operation was begun. It lasted twenty-five minutes and consisted of the removal of dead bone from the hip-joint and the pelvis, and curettage of the old sinuses with the making of a large opening in the left buttock down to the sacrum, allowing free exit to considerable pus. No pain was felt and the patient was with difficulty kept from watching the operative field. Before operation, temperature, 100° F.; pulse, 94; respiration, 22. Two hours after operation, temperature, 98.4° F.; pulse, 92; respiration, 22. Analgesia disappeared in forty-seven minutes. Patient consumed milk two and one-half hours after the operation. No nausea or vomiting, but some headache.

January 16th: Slept well after taking two small doses of acetanilid, sodium bicarbonate and caffeine. January 18: Sitting up in bed; feeling very well; condition of urine about the same. March 20th: Patient up and about the ward and feeling very well. Considerable gain in flesh and strength since the operation.

Case VIII.—H. B., male, aged nine years; a strong healthy boy of nervous temperament. (Parents made a special request that the patient should be given something to prevent pain.) Cocaine analgesia, February 1, 1901. Place of puncture, the lower lumbar region. Amount of cocaine, ten minims of a two-per-cent. solution. Analgesia complete to the level of the diaphragm in three minutes. Operation lasted fifteen minutes, and consisted of a circumcision. Patient had nausea and vomiting a few moments after the injection. No pain or discomfort was experienced. Before operation, temperature, 98.4° F.; pulse, 77; respiration, 28. Two hours after operation, temperature, 99° F.; pulse, 80; respiration, 20. Analgesia completely disappeared in three hours. Severe headache for several hours after the operation. Some vomiting.

February 2d: Feeling very comfortable. February 8th: Patient perfectly well. Wound healed *per primam*. March 28th: Patient continues well.

Case IX.—M. B., female, aged eleven and one-half years; general condition fair. Tuberculous abscesses of foot with tarsal necrosis. Cocaine analgesia, February 7, 1901. Place of puncture to the right between the third and fourth lumbar vertebræ. Amount of cocaine, fifteen minims of a two-per-cent. solution. Analgesia to the level of the diaphragm in two minutes. Slight nausea and retching for a moment five minutes after the injection was completed. Operation lasted twenty minutes, consisting of opening the abscesses and removing carious bone and tuberculous tissue. Before the operation, temperature, 102.4° F.; pulse, 128; respiration, 26. One and one-half hours after the operation, temperature, 101° F.; pulse, 128; respiration, 26. At the close of the operation, twenty-five minutes after the injection, there was absolute absence of pain sense over the entire body. Tests proved also that the analgesia was present in the conjunctivæ, the mouth, on the tongue, and the posterior pharyngeal wall. So far as I am aware, this is the first case recorded where analgesia has been present universally throughout the body. Twenty minutes after the operation was finished analgesia began to disappear. Pain sense returned to the head and upper extremities in thirty-five minutes and completely returned in one hour and five minutes. There was no marked shock or depression of the mental faculties either during the operation or subsequent to it.

February 8th: Had a slight headache, but no nausea or vomiting. Seven and one-half hours after operation, temperature, 103.4° F.; pulse, 144; respiration, 32. Took some milk to-day, but has slight repugnance for food.

February 9th: Slept well. Distinctly better than before the operation. February 10th: Condition greatly improved. Sinus healing. March 1st: Good condition. March 28th: Convalescence uninterrupted.

Case X.—W. E., male, aged seven and one-half years. General condition good. Phimosis and enuresis nocturna. Cocaine analgesia, February 19, 1901. Place of puncture, to the right between the third and fourth lumbar vertebræ. Amount of cocaine, ten minims of a two-per-cent. solution. Analgesia to the level of the diaphragm in six minutes. Patient somewhat hysterical immediately following the injection, but became perfectly quiet before the operation was commenced. Nausea and slight vomiting for two minutes in five and one-half minutes from the time the injection was completed. Operation lasted twenty minutes consisting of a circumcision. Patient had no pain or discomfort. Before operation, temperature, 99° F.; pulse, 100; respiration, 24. Two hours and fifteen minutes after operation, temperature, 99.5° F.; pulse, 98; respiration, 24. Analgesia disappeared in two hours and fifteen minutes. Headache for several hours. Vomited once, five hours after the operation.

February 20th: Complained of some headache during the night. Small dose of acetanilid, caffeine and sodium bicarbonate gave relief. February 21st: No after-effects. February 25th: Up and about, perfectly well.

Case XI.—A. M., male, aged sixteen years. Typical tuberculous child, having considerable kyphoscoliosis in the lower dorsal region, with marked prominence of the lower ribs on the right side. Chronic ulcerated cicatrix on the dorsal surface of the right foot. Cocaine analgesia, February 27, 1901. Point of puncture, to the right between the fifth lumbar and first sacral vertebræ. Needle was blocked by small blood-clot while passing through the soft tissues and was withdrawn. The needle freed from the clot was reinserted between the third and fourth lumbar vertebræ. Amount of cocaine, ten min-

ims of a two-per-cent. solution. Analgesia began in four minutes and extended to the level of the mid thigh in six. The operation lasted forty-five minutes, consisting of the excision of the cicatrix and the covering of the site of the old ulcer by flaps of skin taken from the outer side of the foot and leg. No nausea or vomiting; no pain or discomfort during the operation. Vomited once six hours after the operation and for some hours had headache. Before operation, temperature, 99.4° F.; pulse, 88; respiration, 24. After the operation, temperature, 99° F.; pulse, 84; respiration, 20. After the completion of the operation, tests showed that the analgesia had extended to the level of the nipples in front and behind, and there was motor paraplegia below the level of the hips. These completely disappeared in about two hours.

February 28th: Highest temperature during the night was 102° F.; pulse, 120; respiration, 28. Complains of some pain in the leg, but relieved by small doses of acetanilid, sodium bicarbonate and caffeine. March 2d: Patient seems entirely free from any after-effects. March 28th: Patient's general condition same as before operation. Foot slowly healing.

Case XII.—J. R., male, aged sixteen years; poorly nourished, of low vitality and probably tuberculous. Extreme left talipes equino-varus and an old ulcer with superficial necrosis of the plantar surface of the right os calcis. Cocaine analgesia, February 28, 1901. Place of puncture, to the right between the third and fourth lumbar vertebræ. Amount of cocaine, twenty minims of a two-per-cent. solution. Analgesia began in three minutes and was complete to umbilicus in eight. Some loss of motor power below hips. Operation lasted forty-four minutes, and consisted of the Phelps' operation for talipes on the left foot; old ulcer excised and part of right os calcis removed, with edges of the skin freed so as to make a complete skin covering to the heel. Ten minutes after the operation started, slight nausea and retching. Vomited bile-colored fluid twenty-five minutes later. During period of nausea a weak and rapid pulse was noted, with some cyanosis of the face. A hypodermic injection of $^1/_{100}$ of a grain of strychnine sulphate was given. There was no pain or discomfort during any part of the operation. Before operation, temperature, 98.2° F.; pulse, 90; respiration, 20. Two hours after operation, temperature, 98.2° F.; pulse, 108; respiration, 20. Analgesia completely disappeared in one and one-half hours after the operation, at which time motor power had fully returned to the normal. Two hours after the operation patient ate and retained a light lunch, consisting of bread and egg. Evening, temperature, 101.4° F.; pulse, 142; respiration, 26. Vomited once. Very slight headache.

March 1st: Feeling perfectly well but has some pain in the left foot. Afternoon temperature, 101.4° F. March 2d: Sleeping normally. Appetite good. March 28th: General condition as good as before operation. Feet doing well.

Case XIII.—E. D., male, sixteen years; feeble-minded; external and internal hemorrhoids. Cocaine analgesia, March 2, 1901. Amount of cocaine, twenty minims of a two-per-cent. solution. Place of puncture, to the right between the third and fourth lumbar vertebræ. Analgesia to the level of the diaphragm in two minutes from the completion of the injection. The operation lasted twenty-one minutes and consisted of the usual clamp-and-cautery operation. No pain, nausea, or vomiting. After the operation, the highest temperature was 99.2° F.; pulse, 94; respiration, 22. Analgesia completely disappeared in two hours and fifteen minutes.

March 3d: No after-effects from the cocaine. Slept all night. March 20th: Patient's recovery has been uninterrupted. March 25th: Perfectly well.

Case XIV.—H. C., male, nineteen years of age; fairly well developed, feeble-minded, deaf and dumb, hydrocephalic. A blind external fistula *in ano*. Troubled with frequent formations of pus. Cocaine analgesia, March 2, 1901. Place of puncture, to the right between the third and fourth lumbar vertebræ. Amount of cocaine, twenty minims of a two-per-cent. solution. (The needle had to be passed in twice, as the first time it became occluded by a small blood-clot and the cerebrospinal fluid failed to flow.) Analgesia complete to the umbilicus in four minutes. Operation lasted twenty minutes, and consisted of a division of the sphincter ani and excision of the diseased tissue. Slight nausea and headache, but no vomiting; no pain. Before operation, temperature, 98.0° F.; pulse, 99; respiration, 22. Seven hours after the operation, temperature, 98.6° F.; pulse, 72; respiration, 20. Analgesia entirely disappeared in two hours and forty minutes.

March 3d: Patient seems perfectly well. No apparent after-effects from the cocaine. March 25th: Patient perfectly well.

Case XV.—A. S., female, thirteen years of age; marked idiocy. Gangrene of the left foot. General tuberculosis. Circulation poor and condition bad. Cocaine analgesia, March 7, 1901. Place of puncture to the right between the third and fourth lumbar vertebræ. Amount of cocaine, sixteen minims of a two-per-cent. solution. Analgesia complete to the level of the diaphragm in four minutes. Operation lasted twenty-eight minutes and consisted of an amputation of the leg at the junction of the middle and lower third. No pain or apparent discomfort of any kind. Tests showed that at the end of the operation analgesia was complete over the entire body, except the face, mouth and eyes. Before operation, temperature, 98.6° F.; pulse, 122; respiration, 34. Three hours after operation, temperature, 99.4° F.; pulse, 112; respiration, 36. Analgesia completely disappeared in two hours and twenty minutes from the completion of the injection.

March 8th: Patient retains strychnine, whiskey and fluid diet without difficulty. Com-

fortable night. No nausea or vomiting during or since operation. March 14th: Patient doing well as could be expected. March 25th: Stump slowly healing.

Case XVI.—J. M., male, aged ten years, five months. General condition exceedingly bad. Highly neurotic. Advanced disease of left hip-joint, with a discharging sinus below Poupart's ligament, the opening of which is entirely too small. Has attacks now and again of precordial pain. Cocaine analgesia, March 12, 1901. Place of puncture to the right between the third and fourth lumbar. Amount of cocaine, twelve minims of a two-per-cent. solution. Analgesia to the level of the anterior superior spine in four minutes. The operation lasted four minutes, and consisted of an enlargement of the sinus and the making of a fresh opening for drainage over the trochanter major. At the completion of the operation, the analgesia had extended to the level of the diaphragm. No nausea, vomiting, pain, or discomfort. The patient left the operating-room evidently very little worse for the operation. Before operation, temperature, 99° F.; pulse, 94; respiration, 22. Two hours after the operation, temperature, 98° F.; pulse, 128; respiration, 48. Analgesia disappeared in one hour and a half from time of injection.

March 13th: Has been perfectly comfortable, having experienced no headache. Slept fairly well. Highest temperature, 104° F.; pulse, 150; respiration, 50. Retained strychnine and whiskey. March 14th: Complains of pain in leg. Seems weak, but otherwise well. March 15th: Feeling better. March 23d: Distinctly better than before the operation. No effects from cocaine. Slowly improving. March 28: Much better.

Case XVII.—R. K., male, aged ten years; general condition fair. Tuberculous caries of the ilium with inguinal sinus. Patient was operated on November 2, 1900, subarachnoid injection of cocaine being employed.[1] No effects from previous spinal injection. Improvement has been steady, but the external opening of the sinus is now insufficient for drainage purposes and there is more dead bone to be removed.

Cocaine analgesia, March 14, 1901. Place of puncture to the left between the third and fourth lumbar vertebræ. Amount of cocaine, twelve minims of a two-per-cent. solution. Analgesia to the level of the umbilicus in four minutes. Slight nausea and retching nine minutes after the injection. The operation lasted eight minutes and consisted of enlargement of the outlet of the sinus and removal of dead bone and necrotic tissue. No pain or discomfort. The patient was asked whether, remembering what he had been through before, he feared the operation. He replied, "No, I was not hurt the last time." One hour before the operation, temperature, 100.5° F.; pulse, 90; respiration, 22. Five and a half hours after the operation, temperature, 100.4° F.; pulse, 98; respiration, 22. Analgesia disappeared entirely in one hour and a quarter after the injection.

March 15th: Considerable headache. Vomited several times last night and this morning. March 16th: Effects of the spinal injection entirely gone. March 28: Patient up and about. Doing well.

Case XVIII.—J. O., male, aged ten years; general condition good. Has had several attacks of tuberculosis of the skin which have been successfully treated by excision or cauterization. Has some new areas which have freshly broken out in the neighborhood of the old scars of the left leg and thigh.

Cocaine analgesia, March 21, 1901. Amount of cocaine, ten minims of a two-per-cent. solution. Analgesia to the level of the diaphragm in three minutes after the injection. Vomited three minutes later. Operation lasted nine minutes and consisted of the excision of the ulcerated tissue with the free use of the cautery along the edges and on the surface of the ulcers. No pain or discomfort during the operation, but immediately afterward a slight frontal headache was noted. Patient was thoroughly tested and it was found that the muscular sense, the ability to detect heat and cold and tactile sensibility were not lost. He was able to stand without difficulty and walk across the room. Before operation, temperature, 100° F.; pulse, 108; respiration, 22. Nine hours after the operation, temperature, 100° F.; pulse, 88; respiration, 22. Analgesia entirely disappeared in one hour and a half. Vomited three times during first six hours. Severe headache. Cried out with pain. Hypodermic injection of $^1/_{100}$ of a grain of nitroglycerin gave immediate relief and patient slept three hours.

March 22d: Slept well all night. March 24th: Normal condition except dizziness while walking. March 26th: No effects from cocaine. April 1st: Doing well.

Case XIX.—K. M., female, aged thirteen years; marked idiocy with epilepsy. Bad general condition. Phthisis pulmonalis. Circulation very poor in all extremities. Deep fetid gangrenous ulcer on the dorsum of the foot, which refuses to heal and is steadily increasing in size. Something must be done. Slowly getting worse. Cocaine analgesia, March 1, 1901. Place of puncture, between the third and fourth lumbar vertebræ. Amount of cocaine, fifteen minims of a two-per-cent. solution. Analgesia complete to the level of the umbilicus in three minutes. Operation lasted fifteen minutes, and consisted of the Chopart's amputation. No apparent pain. No nausea or vomiting. Before operation, temperature, 98.5° F.; pulse, 92; respiration, 22. Three hours after operation, temperature, 98° F.; pulse, 72; respiration, 26. During the evening had an epileptic seizure which lasted some minutes.

March 2d: Taking small doses of codeia, strychnine and whiskey. Quiet. March 3d: Do-

[1] For report of previous operation, see *Medical Record*, Vol. LVIII., No. 24, p. 937.

ing as well as could be expected. March 16th: Stump almost healed. March 18th: Refuses to take nourishment. General condition getting worse. March 20th: Phthisis increasing. March 21st: Pulmonary hemorrhages. March 22d: Died.

Case XX.[1]—A. F., male, aged eleven years; general condition fair. Spinal curvature. Tuberculous sinus of knee. Cocaine analgesia, February 15, 1901. Point of puncture in the lower lumbar region. Because of the kyphosis the needle had to be introduced in a very oblique direction. Amount of cocaine, fifteen minims of a two-per-cent. solution. Analgesia to the level of the navel in eight minutes. Operation consisted of enlargement of the sinus and the removal of some dead bone. Four hours before operation, temperature, 99° F.; pulse, 106; respiration, 24. Two hours after operation, temperature, 99.2° F.; pulse, 98; respiration, 22. No pain, nausea, or vomiting. In one hour and fifty-five minutes analgesia completely disappeared.

February 16th: Slept well. Very comfortable. February 17th: Patient up and about feeling perfectly well. March 28th: Sinus almost healed. Recovery uneventful.

The fact that in several cases there had been analgesia above the level of the diaphragm led to attempts to operate upon the upper extremities. The following cases show what success was attained.

Case XXI.—E. J., male, aged nine years and nine months, fair general condition, highly neurotic, advanced tubercular arthritis of the left elbow. October 6, 1899, resection of elbow under ether, took anesthetic badly from the first. As small amount of ether given as possible. The operation was completed with difficulty and before the patient was removed to the ward active stimulation and inversion of the body with artificial respiration were necessary. The respiratory center seemed almost paralyzed. For some hours the patient's condition was considered bad. November 18th: Wound healed well, except a small sinus over the lower end of the humerus.

Cocaine analgesia, November 19, 1900.[2] (*a*) Place of puncture to the right between the second and third lumbar vertebræ. Amount of cocaine, five minims of a one-per-cent. solution. At the end of sixteen minutes from the time of injection no analgesia had become evident. (*b*) Second injection at the site of the first. Amount of cocaine, seven minims of a one-per-cent. solution. No analgesia fifteen and a half minutes from the second injection. (*c*) Third injection to the left between the second and third lumbar vertebræ. Amount of cocaine, eight minims of a one-per-cent. solution. Vomited in two and a half minutes. Presented the same symptoms as in other cases, except there was no true analgesia. Operation was postponed. Before operation, temperature, 98.6° F.; pulse, 96; respiration, 24. Three hours after the last injection, temperature, 99.4° F.; pulse, 116; respiration, 32. Very restless during the afternoon. Complained of headache. Some vomiting.

(The remainder of the solution which was used in this case was carefully tested. It was found to be practically inert. This was the only case where heat was used in the method of sterilization of the cocaine. The second operation was done under the same supply of the drug, except prepared by the ether method.)

Case XXII.—Same patient; general condition good. Small sinus over the end of the left humerus continues to discharge. Cocaine analgesia, February 13, 1901. Place of puncture to the right between the third and fourth lumbar vertebræ. Amount of cocaine, eight minims of a two-per-cent. solution. In three minutes analgesia complete to a point midway between the ensiform cartilage and the umbilicus. At the end of seven minutes nausea and retching for a moment. In nine minutes analgesia complete over the entire body, including the mouth and tongue. Operation lasted seven minutes and consisted of an enlargement of the sinus and the removal of dead bone and tuberculous tissue. Patient was quiet and experienced no pain. One hour before operation, temperature, 99° F.; pulse, 100; respiration, 22. One hour after operation, temperature, 99° F.; pulse, 98; respiration, 26. Highest temperature since the operation, 102° F.; pulse, 108; respiration, 26. At the end of twenty minutes from the time of the injection the analgesia began to disappear about the shoulders and head. Analgesia completely disappeared in one hour and ten minutes. No nausea or vomiting following the operation.

February 14th: Slept well. No nausea, vomiting or headache. Temperature, 99.2° F.; pulse, 94; respiration, 24. February 15th: As well in every respect as before the operation. March 28th: Patient's condition continues normal.

Case XXIII.—A. W., male, aged eleven years. Very poor general condition. Has tertiary syphilis and multiple tuberculous sinuses of the left lower arm and forearm with extensive caries. For months an effort has been made to save the extremity. In spite of tonics there was some diminution in flesh and strength. His condition growing worse. Amputation seems indicated. Cocaine analgesia, February 15, 1901. (*a*) Place of puncture to the right between the third and fourth lumbar vertebræ. Amount of cocaine, twenty minims of a two-per-cent. solution. Analgesia at the end of fifteen minutes not being above the level of the hips, a second injection was determined upon. (*b*) Place of puncture to the left between the third and fourth lumbar vertebræ. Amount of cocaine, ten minims of a two-per-cent. solution. Six minutes after the second injection analgesia was absolute below the umbilicus. As the analgesia did not extend into the upper extremity, amputation was de-

[1] For previous operation under cocain analgesia, see Medical Record, Vol. LVIII., No. 24, page 939.

[2] Reported in a discussion at a meeting of the Medical Association of the Greater City of New York, Dec. 10, 1900.

ferred, it being thought best not to increase further the amount of cocaine which the patient had already received. To have pushed the dose further for experimental purposes would have been interesting, but hardly just under the circumstances. Patient was returned to the ward apparently not affected deleteriously by the injections. Temperature before injection, 99° F.; pulse, 90; respiration, 22. Five hours after operation, temperature, 100° F.; pulse, 122; respiration, 24. There was no nausea or vomiting, and not even pain when the needle was pushed deeply into the analgesic areas. Analgesia totally disappeared in about two hours.

February 16th: Has had no after-effects from the cocaine; slept all night. February 18th: Is in as good a condition as before the injection. February 27th: Chloroform administered, and left arm amputated in its upper third. Enlarged glands in the left axilla removed. March 28th: Patient's general condition has greatly improved since the removal of the arm. Stump practically healed.

Case XXIV.—S. B., female, aged seventeen years (appears at least nineteen). Strong healthy girl suffering from idiocy and sub-acute cellulitis of the left thumb with necrosis. Cocaine analgesia, March 14, 1901. Place of puncture to the left between the second and third lumbar vertebræ. Amount of cocaine, thirty-two minims of a two-per-cent. solution. Analgesia to the level of the hip-joints in five minutes. After fourteen minutes, analgesia complete to the level of the clavicles, in front and behind, including the upper extremities. The operation lasted fourteen minutes, and consisted of an amputation of the left thumb at the lower third of the metacarpal bone. No pain during the incision of the soft parts, but the cutting of the bone evidently slightly painful, although insufficient to cause the patient to withdraw the hand from the surgeon. (During the severing of the soft tissues the patient sang the National air.) At the close of the operation there was some retching, but no emesis. The patient was sent to the ward in good condition, with the analgesia still as complete as at the beginning of the operation. Pain sense returned in one hour. Before the operation, temperature, 98.6° F.; pulse, 94; respiration, 22. Six hours after operation, temperature, 104° F.; pulse, 122; respiration, 24.

March 15th: Patient has experienced absolutely no after-effects of the cocaine, with the exception of a slight headache. March 19th: Patient up and about. Seems perfectly well. Wound healing nicely. March 28: Convalescence uneventful. Stump healed.

General Remarks.

The cases thus described have not been specially selected. Some have been decidedly unfavorable for any operative procedure, and in a few the operation was at best a forlorn hope. By thus testing this method in all sorts of conditions, its proper position will be more quickly established.

No difficulty has been experienced in introducing the needle either in adults or in children. A few times the needle has been clogged by a small blood-clot while the instrument passed through the soft tissues, before entering the spinal canal; examples, Cases II., XI., XIV. A few experimenters, at such times, use the stylet, pushing into the intra-dural cavity whatever is in the needle. This is certainly to be condemned. The withdrawal of the instrument and a fresh introduction is the better plan.

Summary of Fifty Cases.

The following conclusions are made from fifty cases, the above being included in that number:

1. Cocaine is far more satisfactory than eucain. The latter is less potent, more evanescent, the areas of analgesia are frequently "patchy," having the pain sense retained all around them and not being so complete below definite levels. The cocaine produces no more unpleasant after-effects than eucain and is decidedly more reliable.

2. Analgesia to the level of the diaphragm can be depended upon in all cases where a moderate dose of a potent solution of cocaine has been introduced by lumbar puncture. In some the analgesia is sufficient for operation on the upper extremities; examples, Cases IX., XV., XXII., and XXIV.

3. Complete analgesia, including the eyes, mouth and throat has occurred: example, Case IX. It does not entail more severe after-effects than when the lower extremities only are involved.

4. The preparation of the patient as for a general anesthetic diminishes all the unpleasant effects of cocaine and eucain and often prevents them altogether.

5. By moderate doses of bromides before the injection the initial vomiting is frequently avoided and the liability of headache lessened.

6. In neurotic patients there are often hysterical symptoms directly following the completion of the injection, but, as a rule, in a few moments a calm follows and the patient lies perfectly still.

7. Initial nausea and vomiting often occur soon after the puncture, but last only for a moment or two, and usually do not recur during the operation. As consciousness, as well as the muscular power, is preserved, the danger of the introduction of the vomitus into the lungs is practically *nil*.

8. Analgesia lasts from thirty minutes to four hours.

9. Depression after the puncture is inconsiderable. The use of ethyl chloride (Bengue) largely prevents pain when the needle is introduced.

10. The preparation of the patient, the use of nitroglycerin by hypodermatic injection, or the employment of coal-tar products with caffeine,

control the headache, which is in many instances an after-effect of spinal puncture.

11. In a few cases there may be motor paraplegia or vertigo. Both are temporary. Example, Case XI.

12. Spinal puncture has not affected normal or diseased kidneys.

13. Usually the tactile power, muscular sense, and the ability to detect heat and cold are retained. The cautery at a dull red heat causes no pain, while hot water produces marked discomfort.

14. Usually the patient sleeps the first night.

15. There is often a temperature of a few degrees within eight or ten hours of the operation. Whether this is the direct result of the puncture or the effect of psychic disturbances is not determined. The circulation and respiration are not seriously embarrassed.

SOME SOURCES OF ERROR IN LABORATORY CLINICAL DIAGNOSIS.

BY THEODORE C. JANEWAY, M.D.,
OF NEW YORK;
LECTURER ON MEDICAL DIAGNOSIS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

One of the most noticeable developments in medical practice during the last quarter century has been the widespread application of the methods of the natural sciences to the solution of every-day diagnostic problems. The chemical analysis of the secretions and excretions, the microscopical examination of the blood, the search for the bacterial causes of disease by staining and culture have become familiar to us all.

Such advances in knowledge must of necessity lead to greater accuracy in diagnosis, but they cannot, as many think, make an easier road to it. On the contrary each new method requires added skill and added knowledge and can never supplant, but only supplement the old. The foundation must be anatomical in the diagnosis, as in the study of disease, and without physical exploration no investigation of function can be of service. I think the time has come to emphasize the fact that clinical diagnoses cannot be made in the laboratory. A diagnosis must be individual and comprehensive and attained not by analysis alone, but by analysis and synthesis. Only the clinician is in a position to balance all the facts in a given case and to determine their relation to one another. Therefore the first requisite for a diagnostician is not technical skill, but a judicial mind, capable of weighing the value of evidence.

"Sine diagnosis nulla therapeia" is a trite quotation; each of us who undertakes the treatment of disease must be a diagnostician—or a charlatan—none of the latter, I feel confident, will read these words. Therefore as practitioners we must utilize, so far as possible, the results which the laboratory can furnish us. Some of the methods are of such a nature that any one can use them in his office. Of these he must know the limitations and possible errors inherent in the methods themselves. Others require an amount of time, apparatus and technical skill which places them beyond the reach of all but special laboratory workers. Here the practising physician should know the worth of their findings as positive or negative evidence.

It is evident from this that the sources of possible error in the application of laboratory methods to diagnosis are twofold; those due to the methods themselves or faulty technic in their use, and those due to inaccurate reasoning from accurate results. The writer has been fortunate in the opportunity of making, wholly or in part, some fifteen to eighteen hundred laboratory examinations a year for several years, in the consulting practice of his father, where his results were controlled by clinical observation which was available to him. He has thus obtained so large a personal experience of the possible sources of error that he has thought a consideration of the more common ones might prove helpful.

Examination of Urine.—The greatest value of the examination of the urine undoubtedly lies in the direct evidence it may afford of disease in the kidney or urinary passages and of diabetes. To most practitioners this means the application of the familiar tests for the presence of albumin and sugar. They are certainly the foundation of clinical urine analysis and will be considered seriatim.

Tests for Albumin.—Those in most common use are the cold nitric-acid ring test (Heller's), boiling with the addition of acetic or a drop of nitric acid (heat and acid), and the acetic acid and potassium ferrocyanide test. Other reagents less frequently employed are trichloracetic acid, picric acid, bichloride of merury in Spiegler's test and potassio-mercuric iodide in Tanret's reagent.

Errors in Technic.—The most conspicuous of these is a failure to filter the urine. It is absolutely impossible to make a delicate test in an unfiltered urine or with turbid solutions. In the ring tests there must be a sharp line of demarcation between the solution and the reagent. The presence of bile or of urates in large amount renders Heller's test almost useless. Where there is any possibility of the occurrence of albumose, the tube should be warmed, an albumose ring being dissolved while an albumin ring is unaffected by heat. The same holds good for the rings formed by certain drugs, the balsams and rhubarb especially. These, in addition to their disappearance on heating, are usually of a reddish or brown color. The turbidity produced by urates is never at the line of junction of the acid and urine, but forms from above downward. Heller's reaction, in the case of small quantities of albumin, may take as much as fifteen minutes to develop, and the tubes should

not be discarded within that time. In the heat and acid test, the upper layer of urine in a long test tube should be boiled and the acid added and a comparison made with the clear urine below. The faintest turbidity can be detected by examining the tube against a black background —a small book answers excellently—between the tube and the window. With light falling from behind the examiner the test is much less delicate. Tests made by dropping the solution into the urine should always be judged by the side of a tube of filtered urine. Finally, the acetic-acid and ferrocyanide test needs an especial check, that is, comparison, not with clear urine, but with urine to which acetic acid alone has been added. The addition of acetic acid and subsequent filtration has never been of service to me, as the acetic-acid precipitate passes through the best filter paper I have been able to obtain. Both of these reactions can be clearly brought out by the contact method, the acetic acid and solution of potassium ferrocyanide being mixed in proportion of one part of the first to two of the latter. The ring should always be compared with that developed by acetic acid alone. Made with these precautions, a positive result, that is a greater turbidity of an actual precipitate in the urine tested, or a ring in the case of those tests, indicates the presence of some proteid body.

Errors Inherent in the Methods Themselves.—Unfortunately our knowledge of the proteids appearing in the urine is very incomplete. Nucleo-albumin is of the most frequent occurrence, trace of it being demonstrable in nearly every urine as a faint cloud on the addition of acetic acid, with dilution if the urine be concentrated. Next come serum albumin and globulin, the presence of which in spite of the old classification of a certain group of cases as "physiological albuminuria," must probably always be regarded as pathological in the strict sense. Fibrin and fibrinogen, albumoses, egg albumin and casein have been found in special conditions. Perhaps the globulins of the urine are not all the normal serum globulin. The practical problem, therefore, in the diagnosis of disease of the urinary apparatus is the detection of serum albumin and globulin, which can be classed together, and possibly of abnormally large amounts of nucleo-albumin.

What is the value of the common tests for the detection of these albumins? Nucleo-albumin alone is precipitated by an excess of acetic acid in the cold and this test gives positive evidence of its presence. Only very marked turbidity is of any practical importance and this mainly from the error it may introduce into the other tests. In my experience the most reliable of these are Heller's, the acetic acid and potas. ferrocyanide and the heat and acid tests. The ferrocyanide test, made as described, in comparison with the cold acetic-acid test, probably gives the strongest positive evidence of the presence of albumin, but it is the least delicate and the most cumbersome. The heat and acetic-acid test in a proper light is in my opinion the most delicate and the easiest of application, trichloracetic acid and Spiegler's and Tanret's reagents equaling it, but offering no advantage. The absence of any haziness with this test I consider absolute evidence of the absence of albumin. A positive reaction, however, which I find in at least nine out of every ten urines examined, if slight is probably due to nucleo-albumin and is of no significance. Marked turbidity or a flocculent precipitate affords definite positive information. As a general test, Heller's is undoubtedly the most useful. I have seen instances where I felt sure that a faint ring was due to nucleo-albumin, as I obtained a stronger one with acetic acid used in a similar way and had no deepening of the acetic acid turbidity on the addition of potas. ferrocyanide; but these cases are of great rarity. Sahli says that nucleo-albumin may respond to Heller's test. Almost always, however, a true ring, even the most delicate, indicates pathological albumin and its absence, under the precautions given, is valid negative evidence so far as appreciable quantities are concerned.

Significance of the Findings.—May any conclusions be drawn from the presence of albumin in the urine? Emphatically none, except that an albuminous urine is not normal, and therefore a further investigation by other methods must be instituted to determine its source. This may be from inflammatory conditions or hemorrhage anywhere in the urinary tract, from congestion, from admixture with menstrual flow, etc. The microscope gives the most evidence on this point, but the whole examination furnishes subsidiary information. On the other hand, the absence of albumin at one, or even repeated examinations does not at all preclude the existence of kidney disease. The contracting kidney frequently fails for considerable periods to give an albuminous urine. I have seen several cases, within only a week or so, of definite uremic attacks, where the urine was normal. Waxy kidney has been reported without albumin in the urine. Acute nephritis is, of course, excluded by its absence. The greatest significance of a negative test is, however, in cardiac cases, in which it gives evidence of the absence of congestion of the kidney and makes a more hopeful prognosis.

Tests for Sugar.—I think few physicians who have not examined many hundred urines appreciate the numerous errors into which one may be led by that universally employed reagent, Fehling's solution. It is the most delicate test for sugar and certainly the most useful for just one purpose—to exclude its presence. I wish to lay particular stress upon that point, for it has been forced upon me unwillingly. Every one knows that various drugs, rhubarb, salicylates, camphor, chloral hydrate, some of the coal tar series and alkaloids, etc., and even the abundant urates of a concentrated urine, will give some sort of reduction, but until recently I had felt that I could distinguish in most cases between these spurious reactions and the real sugar re-

duction. Unfortunately, a number of careful comparative tests have made me certain that it is impossible, and I now use the test solely for the negative evidence it may afford. No reduction with Fehling's solution invariably means no sugar, a reduction merely indicates the necessity for applying further tests. Therefore I will not take time to speak of wrong methods in using Fehling's solution, for from this standpoint they are unimportant.

The tests which do give positive indications of the presence of sugar are the polariscope, fermentation and the phenyl-hydrazin reaction. The first of these is little used clinically, being too expensive and too cumbersome for most physicians. The second is simple, reliable if one is careful to use fresh yeast and stand the tube twenty-four hours in a warm place and has the advantage, when the Einhorn tubes are used, of affording a quantitative determination, sufficiently accurate for clinical purposes. Where this is desired care must be taken that the urine does not contain over 1 per cent. of sugar, the necessary accurate dilution being made to bring it down to this. The only objection to the method is its slowness and its lack of delicacy.

The phenyl-hydrazin test, when applied after the method of A. Kowarski (*Berl. klin. Woch.*, Nov. 26, 1900), is a rapid means of determining the presence of sugar. The employment of phenyl-hydrazin-hydrochloride and sodium acetate as ordinarily given is most unsatisfactory, but the use of pure phenyl-hydrazin, 5 drops, glacial acetic acid, 10 drops, and sat. sol. sodium chloride, 1 cc. to 3 cc. of urine, boiling vigorously two minutes and letting cool slowly in the air, has given me most excellent results. For bringing to my knowledge this manner of performing the test I have to thank Profs. E. K. Dunham and John A. Mandel.

Significance of Sugar.—I only wish to state briefly what is now becoming well recognized, namely, that the presence of sugar in the urine does not constitute diabetes. Only the persistence of sugar after the reduction of the carbohydrates in the diet to a small amount can warrant that diagnosis. For the discussion of alimentary glycosuria and the other more transient forms I would refer to the books upon that subject, especially to Von Noorden's last edition of his work, "Die Zuckerkrankheit und ihre Behandlung."

Quantitative Urine Analysis.—Many physicians appreciate that quantitative estimations demand a sample of mixed twenty-four-hour urine for their performance, but do not realize that even the most ordinary test is of little value if made with the urine passed at one time alone. Unless a fairly representative specimen of the daily excretion is obtained no conclusions at all can be drawn from the absence of sugar or albumin, nor can much be inferred from their presence. A representative specimen should mean the mixed urines passed on at least three different occasions during at least twelve hours. An excellent method, where a twenty-four-hour specimen cannot be obtained, is to take equal parts of the water passed in the late afternoon, before retiring and on rising in the morning. Even with such a specimen, however, careful quantitative methods should not be used, as the results may be misleading. The simplest quantitative method, and it is strictly such, is the estimation of the specific gravity. The only common source of error in the use of the urinometer is a neglect to make the correction necessary for changes in temperature. The instruments are graduated at a certain temperature, usually at 15° C. (59° F.), while the average room temperature is 20° C. (68° F.). The correction being 1 for every 3° C. (5.4° F.), a urine giving a reading of 1,012 at 68° F. with one of these instruments really has a specific gravity of 1,015. Beside this it should be borne in mind that quantity and specific gravity bear an inverse relation to one another and are meaningless when considered alone. The two together give the total solids excreted.

Obtaining an accurate twenty-four-hour specimen from patients not confined to bed is a matter of considerable difficulty. In spite of all explanations they often will not use the requisite care. This at the outset introduces a possible error into all quantitative methods employed, and it is to my mind an explanation of some of the anomalous results obtained.

One of the commonest errors in connection with the specific gravity is to conclude that a urine does not contain sugar if it is below some arbitrary point, 1,030 or 1,025 or even 1,020. Some such rule is a tradition in many hospitals and its fallaciousness should be understood. I have seen sugar urines a number of times with a gravity of 1,015. Some have contained not traces, but as much as 1 per cent. of glucose. Another mistake of opposite character is the failure to recognize the significance of urine of constant low gravity and increased quantity, if albumin be not present. Such urine points strongly to the existence of the contracting kidney, one of the most frequent types of chronic Bright's disease, and should always lead to a thorough examination of the patient, especially with reference to the presence of a hypertrophied heart and high arterial tension.

The quantitative determination of urea, or rather total nitrogen, by the hypobromite method, as in the Doremus, Squibb and other uremometers, is simple and sufficiently accurate for clinical purposes. Only the total amount excreted in twenty-four hours is of any value. The most frequent cause of inaccuracy comes from decomposition of a twenty-four-hour specimen in hot weather, the loss from this being considerable. The urea excretion is so closely dependent upon the diet and other factors that I consider it a mistake to draw many conclusions even from a much reduced amount at a single examination. For practical purposes the total

solids, as indicated by the quantity specific gravity ratio, afford as much and less often misleading information.

Occasional Tests in Common Use.—Of these the Ehrlich diazo-reaction and the tests for bile and indican are most frequently employed. The limits within which the first mentioned can be utilized for the early diagnosis of typhoid fever are becoming well recognized. Emphasis should be laid upon its being considered as corroborative evidence of typhoid only when found in the first week or ten days of a febrile affection.

The tests for bile are apt to be conspicuous by their absence. Small amounts of bile in the urine can be easily detected by Gmelin's test and should always be suspected when the foam is at all yellow. The staining of cells and casts yellow, as seen under the microscope, is an excellent indication of its presence. The finding of bile is important for diagnosis and it should not be overlooked.

The practical value of the examination for indican is so slight and the diagnostic problems connected with it are so complicated that I shall not speak of it.

Microscopical Examination.—No error could be greater than to consider any urine examination complete without the use of the microscope. A thorough microscopical examination requires a proper collection of the sediment, preferably by centrifugalizing, or if that is impossible by allowing the urine to stand at least six hours in a conical glass. Many things of importance will be overlooked if this is not made a matter of routine, notably casts, when not numerous, and a few red blood-cells, which in many cases aid greatly in the discovery of renal calculus as the cause of obscure one-sided pain in the back or abdomen. This condition I am confident is frequently overlooked. The foreign substances which find their way into specimens are many and often lead to confusion; but it is not within the scope of this article to treat of the possible errors in observation. Only a personal experience can teach one their nature. Certain points, on the other hand, which have made a considerable impression upon me, do not seem adequately brought out in the current text-books. One of these is the occurrence of calcium oxalate in a form which closely resembles a red blood-corpuscle in size and shape. It appears perfectly circular and can only be distinguished by its darker more refractile outline, its greater variation in size and usually by the presence of a dark dot at the center. The association of typical octahedra is helpful, but blood-cells may be present as well, and close observation is necessary to be sure of a discrimination. Certain yeast (torulæ) may also be confused with red cells, unless one notes the budding forms. Another point is a simple method for getting rid of the excess of amorphous urate deposit, which in winter often obscures everything in the microscopic preparation. I pipette off the sediment from the urine into a test tube, add an equal volume of water, warm gently until the urate cloud disappears and then centrifugalize. Simply warming will not prevent the rapid reappearance of the turbidity, but the dilution has always answered to keep all in solution. This method is, of course, chiefly of use when all the sediment can be quickly recovered with the centrifuge, but could be applied in a conical glass by using larger quantities.

The presence of casts without albumin has been denied by Simon, who says that he has never met with the condition since using the trichloracetic acid test. The occurrence is undoubtedly of considerable rarity, but I have met with several cases in which I used particular pains in applying the trichloracetic acid test, and could not elicit even a faint haziness. Such findings illustrate the necessity for making one's observations all independent of each other.

The examination of urine for tubercle bacilli should not be undertaken by any one who has not had considerable experience in the identification of the tubercle bacillus in sputum, etc. Much is said of the possibility of confusion with the smegma bacillus and the inadequacy of any method except animal inoculation for their differentiation. I do not feel qualified to speak on this point, for I have not yet met with tubercle-like bacilli except in cases of clinical genito-urinary tuberculosis.

Urinary Diagnosis.—Given accurate and complete observations, are errors in diagnosis often made? Some, I fear; especially when the clinical signs and symptoms are not given their due importance. Glycosuria, for instance, is too often called diabetes. The presence of albumin and casts is frequently considered direct evidence of nephritis, when it may be but the sequence of congestion dependent upon a weak right heart, primary, or secondary to mitral or lung lesions. A few casts may cause an albuminuria to be thought of renal origin, when the presence of blood-cells or pus-cells, if given just weight, might place the more important lesion in the pelvis of the kidney or bladder. Such mistakes are always possible to one who seeks a diagnosis from less than a complete consideration of the whole case, and this cannot be obtained in the laboratory.

Examination of Sputum.—Many physicians fail to realize that except in the diagnosis of tuberculous disease, the microscopical investigation of the sputum can give any information of practical value. I should be glad to call their attention to the frequent help that examination of the unstained expectoration may afford. The association with asthma of Charcot-Leyden crystals, more rarely of Kurschmann's spirals, is a strong point in its diagnosis. The more recently described occurrence of large numbers of eosinophilic cells in asthma sputum is still more striking and the double-staining, with eosin and methylene blue necessary to demonstrate them, is simple. The condition most frequently confused with phthisis is the chronic congestion of the lungs due to mitral disease, especially mitral

stenosis. These cases have continued cough, dyspnea, often hemoptysis and loss of weight. The physical exploration of the lungs will not afford any reliable evidence for differential diagnosis; that of the heart, if mitial stenosis be discovered, makes tuberculosis improbable. The sputum, however, gives the most definite information and that not alone by the absence of tubercle bacilli, but by the strong positive evidence of the large cells filled with brownish pigment, which are usually present in considerable number.

Staining for pneumococcus and streptococcus, Pfeiffer's influenza bacillus, etc., has not demonstrated any great practical result, the clinical diagnosis being more satisfactorily made from the other features of the diseases. Rare organisms, such as streptothrix and actinomyces, ova, etc., occasionally give the clue to unusual conditions and should be considered where no ordinary cause can be determined for marked pathological changes in the lungs. In the same category should be placed malignant growths, which, however, seldom give aught but negative evidence in the sputum.

Staining the Tubercle Bacillus.—The common methods, Ziehl-Nielson, Gabbett's, etc., need only to be used accurately to give satisfactory results, but careless staining is a simple waste of time. The most frequent faults are insufficient staining, which leads to a failure to find the bacillus, and incomplete decolorization, which invites confusion with other organisms retaining the red color. The latter is the more serious mistake. If it be borne in mind that the bacillus tuberculosis has a distinct form and that it is as erroneous to call any bacillus of red color the tubercle bacillus as to call any white animal a polar bear, the chance of error would be materially diminished. The use of dirty cover-glasses and slides, needles or dishes may account for some reports of tubercle bacilli in cases which have proven the falsity of the microscopical diagnosis. I do not believe that any slide, cover or receptacle for the sputum should ever be cleaned and used again for this purpose, as the seriousness of the question at issue, to my mind, outweighs any considerations of petty economy. In receiving reports from another examiner, especially from a large laboratory, the physician should always bear in mind the possibility even of clerical error or substitution of one specimen for another, where the microscopical belies the clinical diagnosis.

The more common negative report, where tuberculosis is unquestioned, arises oftenest from the examination of sputum which has not come from the chest, either because the patient has failed to bring a proper specimen, or the examiner has not selected a proper portion for spreading. Patients should be carefully instructed to bring sputum raised from deep in the chest, the early morning secretion is usually best, and no pains should be spared to pick out one of the little grayish particles, or lacking this some muco-purulent streak. This can only be done from a thin layer of expectoration on a black ground. I know nothing more satisfactory for this work than the turned wood sputum boxes, with a water-tight black varnish inside, designed by Dr. Stuart Hart and sold by Lincoln & Luchesi. They, with their contents, are burned after examination. With these precautions, a negative result will be less frequent; but there are undoubtedly a fair number of cases of pulmonary tuberculosis in which tubercle bacilli cannot be demonstrated, even after several examinations. Therefore it should always be borne in mind that only positive findings, free from sources of error, are of absolute diagnostic significance.

Examination of Blood.—The value of the study of the blood as an aid to diagnosis has been fully demonstrated within the last few years. Its practice, however, requires a trained microscopist, and the majority of practitioners are forced to have recourse to the laboratory specialist to make such examinations for them. Unfortunately, all who are now willing to undertake blood examinations have not reached the superhuman condition of infallibility, though their reports are apt to be considered final. The practitioner here, as elsewhere, should accept no diagnosis without a full consideration of the clinical evidence and should be able to understand the results, if not to practise the methods of hematological work.

Quantitative Methods.—The ones in common use are those for the estimation of hemoglobin and specific gravity and the counting of the red and white corpuscles.

Errors in the Use of the Methods.—The error incident to any test which requires the matching of shades of color is naturally considerable and varies with different persons. The determination of the percentage of hemoglobin by the ordinary methods, Von Fleischl, Gowers, etc., therefore, can only be approximate, but in most cases is sufficiently accurate for clinical purposes. I have never thought the specific-gravity method an efficient substitute, and the improved Von Fleischl-Miescher hemoglobinometer requires much more time than its results are worth. In cases showing a very low hemoglobin content the error is much increased. Some bloods also are of a color impossible to compare with the standard; this is especially notable in leucemia, the results here being almost worthless. The counting methods are much more accurate and in careful and practised hands their results can be accepted without hesitation for the drop of blood examined. Much is said in books of the necessity for scrupulous cleanliness in order to obtain absolute contact between cover and slide in the Thoma-Zeiss hematocytometer. Cleanliness is of course essential, but the greatest obstacle to the attainment of the desired Newton's rings I have found to be, not a thin film of grease, but large obvious particles of dust. For this reason I have for several years made a camel's hair brush an essential part of the outfit for

blood-counting, and by dusting slide and cover with it just before using, perfect contact is obtained. I consider it one of my most useful instruments, for it stands me in equally good stead in making blood-films for staining or examination in the fresh state.

Morphological Examination.—This, whether in the fresh state, or by the various general and special staining methods is an essential part of any blood-examination. Without it no count has any value. In this way only can leucemia be differentiated from a leucocytosis, or the malarial organism be discovered, or the diagnosis of pernicious anemia be confirmed. The faults in the preparation of stained specimens can only be learned by personal experience, and the same is true of most of the errors in observation. A few of them may, however, be advantageously pointed out.

Errors of Observation.—The most common of these center around the malarial organism. What I have said of the tubercle bacillus applies with equal force here. The malarial organism has a definite form at each period of its development and no one should attempt its identification without familiarity with its characteristics. The common vacuoles within red cells, blood-plates, masses of extraneous dirt, are too often called plasmodia, and that in cases where good clinical observation should make a diagnosis of malaria untenable. On the other hand, the small hyaline forms are frequently overlooked and crescents may be so rare that several examinations are needed to discover them. Only a very competent observer should make a diagnosis from the presence of unpigmented or extracorpuscular forms, except the crescents and ovoids. The new polychrome methylene-blue stain just perfected by Dr. L. B. Goldhorn places the staining of the chromatin of the parasite within the ability of all and should safeguard from many former errors. One cause of failure to find the organisms may be the selection of a wrong time for the search. The most favorable time is usually about eight hours before the chill, the parasites accumulating more in the internal organs at the time of segmentation. In doubtful cases examinations should be made at different periods. In the estivo-autumnal form even the best microscopist may be unable to arrive at a diagnosis for several days, as the parasites may be extremely scarce in the peripheral circulation.

Errors of observation regarding the classification of nucleated red cells and of leucocytes are possible, but fortunately untrained men less frequently attempt the diagnosis of the anemias. Even among hematologists there is not a unaminity of opinion regarding the exact limits of certain of the cell forms. The differentiation of leucemia from leucocytosis should, however, be made by even a novice in blood-work, if he will only bear in mind that the increase in leucocytosis involves the polymorphonuclear, in the leucemias, the mononuclear leucocytes. The Widal reaction and blood-cultures should not be attempted outside of a well-equipped bacteriological laboratory.

Errors in Estimating the Value of the Evidence Obtainable From Examination of the Blood.—These are frequent and at times serious. In the first rank come the mistakes in the diagnosis of febrile affections, especially when remittent or intermittent in type and unaccompanied by well-marked local symptoms. In this class of cases the blood-examination may be of great assistance. Finding the malarial organism makes, of course, a positive diagnosis. A negative result, however, has only a relative value, depending on the care of the observer and the corroborative findings. A definite leucocytosis combined with an absence of plasmodia is the strongest evidence against the existence of malarial infection and should discredit the diagnosis of malaria in almost every case. The leucocytes should always be counted when the parasite is not found. On the other hand, if there be no leucocyte increase, the question of typhoid fever or tuberculosis arises, especially the former. The Widal reaction should then be tried, but unfortunately it is absent in many cases of typhoid fever during the early period when the diagnosis is doubtful, and a negative test has absolutely no value as evidence. In such cases cultures from the stools and the diazo-reaction in the urine may prove useful, but the clinical course, properly studied, will afford the most reliable indications.

A marked leucocytosis is a sign which should never be neglected. In continued fevers it always points to the existence of sepsis, and unless there are well-marked complications of an inflammatory nature it should lead to a careful revision of a diagnosis of typhoid fever. In these cases of obscure septic conditions errors are common and every means of investigation should be used. In the decision as to operation for supposed appendicitis, I am convinced that the count of the white cells, especially as to an increasing leucocytosis, should be given more weight than at present. Unfortunately, leucocytosis cannot be accorded implicit confidence as a sign of inflammatory trouble. On one hand, it is from time to time absent in severe cases, as, for instance, of general peritonitis or pneumonia or diphtheria; in quite a proportion of patients with ulcerative endocarditis I have failed to find it; on the other hand, very exceptionally, it is found in early typhoid fever. But in the main he who avails himself of the information the white cells afford will avoid far more errors than he will fall into.

The value of the Widal reaction has been so much discussed in special papers that I will not speak of it, except to call attention to the possible, if slight, danger of confusion of specimens in large laboratories. I have known one case in which a laboratory diagnosis of typhoid led to the overlooking of a large internal abscess for three weeks, the explanation probably being a mistake of that kind. I feel strongly that no phy-

sician should allow a laboratory to make a diagnosis of typhoid fever for him, and any such diagnosis by a laboratory should discredit it.

In the field of the true blood-diseases the thing lies somewhat differently. Here the main, sometimes the entire diagnostic evidence is found in the blood, and the opinion of the specialist in such diseases should have the greatest weight. The evidence may be either positive or negative, the latter having especial importance in distinguishing pseudoleucemia from chronic lymphatic leucemia.

Examination of Stomach Contents.—The qualitative and quantitative methods used in the examination of gastric contents are for the most part sufficiently accurate for clinical purposes; that is, the errors in drawing conclusions from the results far outweigh most of the errors of observation. The fundamental points in the quantitative methods are, of course, the test meal and the time of its removal. In order to obtain comparative results these factors should be the same in every case, within certain narrow limits. The finding of lactic acid, for instance, has no meaning if milk has been taken; this most often occurs from the patient using a roll made with milk. Another obvious prerequisite for accurate results is that the contents of the stomach be obtained without the addition of any water.

Töpfer's method as given out by him included the use of alizarin as an indicator. I have not found that any reliance could be placed upon it and have abandoned it, using Congo red to estimate the total free acid and acid salts. The end reaction of dimethyl-amido-azo-benzol was found by Dr. J. S. Thacher, in a set of experiments at the Presbyterian Hospital Pathological Laboratory, to be an orange red and not the standard yellow in the presence of free lactic acid. This should be borne in mind and lactic acid tested for before proceeding to the titration. If present, the soda solution should only be added until the color changes from scarlet to orange red.

The usual tests for lactic acid, Uffelmann's, Kelling's, etc., are subject to so many errors when applied to the filtered gastric contents direct that a positive reaction should not be considered due to lactic acid unless it be corroborated by a test made in a solution of an ether extract of the filtrate.

The test with iodo-potassic-iodide for starch and erythrodextrin I consider capable of affording useful subsidiary evidence and I think it should not be omitted. An occasional test, which should always be applied when there is a suspicion of altered blood, in vomit especially, is Teichmann's for obtaining hemin crystals.

Errors in Reasoning.—The most that we can obtain by our analysis of gastric contents is a functional diagnosis. In most patients with disorders of the stomach the functional disturbance is the disease; in some, however, it is the symptom of organic changes in the organ. The presence of blood, if we can prove that it has come from the stomach, of necessity indicates some organic lesion, be it ulcer or cancer, or a congestion secondary to cirrhosis of the liver or cardiac disease. Mucus in any quantity, especially if it contain leucocytes and epithelial cells when examined microscopically, points to a catarrhal process. Apart from these the laboratory affords no direct light on the causes underlying the disturbance of function, and in many cases of dyspepsia the gastric secretion will be found normal. Hydrochloric hyperacidity is strong corroborative evidence of ulcer of the stomach only in conjunction with stronger clinical evidence, and the same is even more true of the absence of free HCl and presence of lactic acid, once hailed as a certain diagnostic sign of cancer.

Even the discrimination of the exact disorder of secretion present requires care in reasoning. An increase in total acidity above the normal may be due to increase in HCl or organic acids, and a complete examination alone is of value. Where there is no hyperacidity a condition of hypersecretion may be present. A large amount of unconverted starch gives some indication of this, showing an early inhibition of salivary digestion. Sometimes an entire absence of secretion and digestion may be found, where the explanation is a nervous inhibition of secretion due to the effect of the awaited examination. The stomach is so closely related to all the other organs of the body and is so influenced by the nervous system that the most searching examination of the physical and psychical condition of the patient can alone guard against serious errors.

In conclusion I would crave indulgence for the many inadequacies in the discussion of the subject, which are inseparable from the standpoint of personal experience, necessarily incomplete, from which I have aproached it, and trust that the consideration of certain of the sources of error in the great field of the clinical laboratory may help some to a more just appreciation of its scope in diagnosis.

36 West Fortieth Street.

MEDICAL PROGRESS.

Chemistry of Blood During Fever.—A careful chemical examination of the blood of a patient who exhibited febrile periods interrupted by afebrile intervals has been made by K. Stejskal (*Zeitschft. f. klin. Med.*, Vol. 42, 3 and 4). During the fever there was found a reduction of proteid and dried residue, fat, cholestrine, iron and chlorine compound while water, calcium, potassium and total ash were increased and the lecithin and sodium remained normal. With serum alone there was a diminution of all ether extractives and chlorides and an increase of potassium. The red cells were deficient in albumin, cholestrin and lecithin and richer in water and salts. Their weight has increased through imbibition of the plasma. All these changes, the author thinks are due to the temperature alone.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 4, 1901.

ASSOCIATION OF AMERICAN PHYSICIANS.

The sixteenth annual meeting of this distinguished body was a memorable and noteworthy occasion. The attendance was excellent, the program was most interesting and the discussions spirited and awakening.

Comparisons are invidious, but certain of the papers presented were worthy of special praise as offering not so much technical dissertations on recondite and unusual subjects, but practical considerations of fundamental and ever-present problems.

Dr. C. A. Herter of New York read a highly interesting communication on the relations of acid intoxication to the development of diabetic coma. He showed by specially devised chemical methods that the amount of the organic acids might be accurately measured and that as the amount of these organic acids increased and were not neutralized by the bases, formed in metabolism, the danger of coma grew more imminent. These methods offered a practical method of prevising the occurrence of this dangerous complication and offered a hint for the beginning of active treatment.

The papers of Drs. Barker, Novy, and Flexner on their recent investigations on plague in San Francisco were noteworthy. The work done by this Commission merits the highest praise and its members well deserve the thanks of the country at large for their labors. The stamping out of the plague in this country can now be assured because of the suggestions made by the Commission to the health authorities of California.

Drs. Reed and Carroll had the occasion to further supplement their work in Cuba, and from the results more recently announced it may be asserted with confidence that an important etiological factor in the spread of the scourge of yellow fever has found a definite solution. It may be mentioned in passing that the soldiers of the United States who submitted to the experiments are as real heroes of the Spanish-American War as those that indulged in the horrors of battle.

The proceedings of this meeting of the Association will go down in history as embodying some of the most important contributions the science of medicine has ever received.

THE PROTOZOON OF CANCER.

Needless to say Dr. Gaylord's article on the "Protozoon of Cancer" in the May number of the *American Journal of the Medical Sciences* will attract widespread attention. We may still hesitate to accept the opinion that cancer is really on the increase in the alarming degree mortality statistics in this country and in England seem to show, but there is not the slightest doubt that the mystery of the cause of cancer is the most important pathological problem before modern medical science. So many futile attempts at its solution have been made, so much time has been unsuccessfully devoted to its investigation by the great authorities in pathology, that there is now a natural skepticism aroused by any claims of definite results. With this feeling most of Dr. Gaylord's readers will approach his article.

This much is evident even on a cursory reading. His work has been well done. We may be proud to have the results of Dr. Gaylord's researches go forth to the medical world as the type of work accomplished by American investigators under favorable circumstances. The *American Journal of the Medical Sciences* is the most widely read by scientific medical circles in Europe, so that we can be sure that the article will not only attract attention, but

evoke the criticism without which no medical work goes on to its perfect evolution. New light has undoubtedly been thrown on the cancer problem and the State of New York, by whose subvention the laboratory researches have been made possible, may well be congratulated on the fact that one of the first appropriations made for the investigation of a special subject in medicine has been used so faithfully and, as it would seem, with so much promise of ultimate benefit for the race. The money has been well invested and the attention of philanthropists can scarcely fail to be attracted to the importance of material aid for the furtherance of similar researches.

With regard to Dr. Gaylord's article it may be said, first, that his review of the work of others in the investigation of cancer etiology has been not only complete, but eminently fair, and impartial and, second, the conclusions based on his own work, as far as its ultimate results may be anticipated at this stage of the investigation, are modest and unassuming. Certain of his observations go far to overcome prejudice as to the insolubility of the cancer mystery. The fact that the supposed parasites can be seen without staining, for instance, tends at once to reconcile the reader to their probable significance. So many mistaken claims in cancer etiology have been founded on artefact appearances due to elaborate staining methods that this latest observation is at least refreshingly novel. The fact that the appearances thought to be micro-organismal resemble fresh fat droplets, yet prove after the application of the ether and osmic-acid tests to be composed of other material, has not much significance in itself. Some unusual form of degeneration might be expected to occur in cancer. When this observation is, however, taken in connection with the fact that the number of such bodies present increases very materially during twenty-four to forty-eight hours after the removal of the malignant tumor, there seems good reason to think that we are in the presence of a far-reaching discovery.

So-called fatty degeneration of carcinoma is not infrequent and Dr. Gaylord now interprets the appearances that are presumed to demonstrate the condition as really due in some part to the presence of the various forms of an organism of cancer. These have hitherto been mistaken for fat droplets and for infected epithelial cells which were supposed to be in an advanced stage of fatty degeneration. The centers of carcinomata that have undergone degeneration to such an extent that the contents are fluid, thus producing the so-called "cancer milk" of the older writers, are in Dr. Gaylord's opinion practically pure cultures of the cancer micro-organisms, and he adds, "The fluid from malignant ovarian cysts likewise contains a large number of the organisms and the peculiarly characteristic mush found in the cavities of certain adenocarcinomata of the ovaries is likewise largely composed of the various forms of the parasite."

Dr. Gaylord has not succeeded in cultivating the micro-organism he has been observing. As he has employed sixty-four kinds of culture media, it would seem that the question of the microbe being a saprophyte is definitely settled. These experiments would also seem absolutely to preclude the idea of the microbe under observation being a yeast. The protozoon nature of the organism might thus be assumed by exclusion. In confirmation of the theory of the protozoon character of the cancer parasite, Dr. Gaylord has made some interesting comparative observations with certain appearances recently described in vaccine lesions. Comparative tests made with staining methods show that the half-grown forms of the vaccine organism, as described by Gorini last year, are very closely related in appearance to the bodies seen by Plimmer and Russel, English observers whose work has been confirmed by Dr. Gaylord's researches. The protozoon forms in carcinoma all have their prototypes in the various stages of development of the vaccine organism.

Our two greatest pathological problems, the etiology of smallpox and cancer, seem to be approaching solution together. Dr. Gaylord has been able to produce some apparently malignant neoplasms in animals. The demonstration of his micro-organism in the circulation of animals suffering from cancer cachexia is interesting and eminently suggestive. The cause of cancer cannot be said to be definitely discovered, but an important step forward in our knowledge of cancer etiology has been made. That this should come as the result of the coördination of the observations of investigators in many countries adds to the probability of ultimate success. Medical discoveries have never been made out of the whole cloth of absolute invention. They have ever been,

just as in this case, foreshadowed by many observers before being ultimately formulated in their true expression.

THE PHYSICIAN, A DISREGARDED FACTOR IN MEDICAL PROBLEMS.

The recent death of the Bell Bill limiting the practise of so-called "Christian Science" but confirms the well-known and often-stated fact that legislation alone cannot prevent abuses in the medical world. In discussing the time-worn topic of the regulation of the dispensary abuse the general tendency has been to blame the pauper element among those who are not dependent upon charity for availing themselves of the gratuitous medical advice proffered by the dispensaries, and to advocate careful investigation of their financial status.

While acknowledging the advisability of this method it must not be overlooked that the members of the profession can do much to aid the movement by their personal attitude, in convincing those who are in a position to recompense a physician that the acceptance of charity treatment lowers such an individual in the public estimation. The investigation of applicants is hindered by the wish of the dispensaries to present a creditable record of the number of "worthy poor treated, and incidentally by the desire to obtain a more generous share of the city appropriation for the treatment of such cases.

Fully as important a factor, however, is the attitude of the medical men themselves in this matter, and by their coöperation alone can the abuse of dispensary charity be regulated. Patients are allowed to receive treatment "for teaching purposes" although they may refuse to appear before the classes, or through carelessness as to their financial condition, or in some cases in the hope that they may eventually be turned toward the office of the attendant.

The present overcrowding of the medical profession leads to the necessity for some form of advertising. As the number of physicians in the city increases, so does that of the dispensaries and hospitals, nominally for charitable purposes, but often really for the sake of giving places as attending physicians. This in turn leads to the admission of unworthy applicants as patients in order to fill the dispensary. In favor of the multitude of these institutions, however, may be raised the just argument that comparatively few of the horde of men annually graduated can secure the necessary education given only by a resident service in a good hospital, and hence must obtain what practical experience is possible by dispensary service, while the confiding public gradually affords opportunities for learning the clinical features and treatment which theoretical instruction cannot convey. Another, and an almost unanswerable argument in favor of the admission, without thorough investigation, of patients who apply at dispensaries is the fact that many of those who can afford the luxuries of life yet still demean themselves to accept charity treatment at a dispensary, are of such a moral caliber that they would cheat a private physician out of his time and money by intentionally neglecting his bills.

The remedy for the dispensary abuse includes not only an examination of the financial condition of applicants, but also restriction of the number of graduates from the medical schools. As competition diminished the necessity for cutting rates, advertising through dispensary positions, etc., would also decrease. Such restriction must necessarily be brought about by more stringent requirements by the medical schools themselves. As long as they continue to graduate any but those best qualified by nature and education for the duties of the medical profession, just so long will the ranks of that profession be overcrowded and this overcrowding with incompetent men merely aids the existence of quacks, "healers," and others who pretend to possess supernatural powers in the treatment of disease.

The mistakes of regular physicians are what drive many a patient to the quack, and anything that will improve their diagnosis and treatment will go far toward removing this support of the powers of darkness. This is best obtained by elimination. The tendency of medical institutions of learning to fill their halls is most natural. A large attendance increases the reputation of the college and last, but not least, furnishes the support without which the maintenance of these institutions would be impossible. Again, it would be held that were the standard of medical education in this city raised it would not affect outside institutions and the city would still be flooded with the products of diploma-mills. Such an argument is not conclusive, as a beginning must be made in any movement and this can nowhere be done better than in the largest and most prolific of medical centers in this country. When the public realizes that the standard of certain institutions is high they will eventually

be more likely to demand men from these sources.

And how is this result to be accomplished? Let those charitably disposed give for the endowment of existing medical institutions, rather than for the erection of new buildings to bear their names, and a serious obstacle in the way of elevation of the standard of the profession will be removed. And let the members of that profession urge the importance of this point upon their would-be benefactors. The true philanthropist will consent, the egotist will demand the construction of a permanent memorial to himself.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—The Section on Otology meets Wednesday, May 8th. Dr. E. W. Pyle will read a paper on "A Correlation of One Hundred Successive Mastoid Operations." Section on Pediatrics on Thursday, May 9th. Dr. W. S. Bainbridge will read a paper on "Spinal Analgesia in Twelve Operations on Children under Three Years of Age." Dr. J. F. Terriberry will show a case of double birth palsy; Dr. J. H. Larkin will report a case of hypertrophic pyloric stenosis; Dr. W. S. Bainbridge a case of double strangulated hernia at four months; operation and recovery; a case of cancrum oris; operation, recovery. Drs. M. Nicoll, Jr., and A. J. Lartigau will present a "Preliminary Report on an Investigation of Adenoids with References to Tuberculosis"; and Drs. W. L. Carr and Samuel Pierson will report a case of general subcutaneous emphysema.

At the meeting held May 2d, the following candidates were recommended for election to Resident Fellowship: Drs. S. A. Brown, W. H. Caswell, J. J. Higgins, John Horn, P. D. Kerrian, C. A. McWilliams, and F. F. Ward.

Gibbs Memorial Prize Fund.—The Trustees of the Academy announce that Mrs. Sarah Barker Gibbs and Miss George Barker Gibbs have given $10,000 to be invested for the establishment of the Edward N. Gibbs Memorial Prize Fund. The income is to be awarded triennially to the physician of regular standing in the medical profession of the United States who shall present the best original essay on the etiology, pathology and treatment of diseases of the kidney.

Yale Commencement Speaker.—Prof. Edmund B. Wilson, of Columbia University, will be the commencement-day speaker at the Yale Medical School.

New York State Medical Society.—At the ninety-fifth annual session of the Medical Society of the State of New York held at Albany, New York, January 29, 30 and 31, 1901, it was moved and unanimously adopted that in order to increase the facilities for becoming permanent members of the Society, each County Society should be allowed to send five times the number of delegates it had formerly sent to the State Society. These delegates are elected for a term of three years and are eligible for permanent membership if they register twice during that time. This will make the number of delegates from the County Society to the State Society 750 in all, or one delegate for every eight or nine members of the County Societies without increase of expense to the County Societies.

It was further agreed in response to a widely-expressed desire, that the Society hold a semi-annual meeting in the City of New York in the early autumn to be devoted entirely to scientific work and social intercourse. The officers of the Society announce that they have engaged the New York Academy of Medicine for this purpose where a meeting of two days' duration will be held October 15, 16, 1901.

Members wishing to read papers are requested to communicate with Dr. Nathan Jacobson, 430 S. Salina street, Syracuse, N. Y., and information of any other nature can be obtained from Dr. Frederick C. Curtis, Secretary, 17 Washington avenue, Albany, N. Y., or from Dr. Frank Van Fleet, Associate Secretary, 63 East 79th street, N. Y. City.

It is further announced that the Society will tender a reception to its members, delegates, and guests, on the evening of October 15th at Delmonico's. Tickets of admission to this reception will be furnished without cost to all who register at the semi-annual meeting as well as to the Society's guests.

Pathological Staff Resigns.—The entire corps of associates and assistants to Dr. Ira Van Gieson, Director of the Pathological Institute of New York, handed him their resignations on April 30th. This action was intended to show their sympathy for and loyalty to Dr. Van Gieson, whose removal was ordered by the Commission in Lunacy to take effect on May 1, 1901. Dr. Van Gieson has begun suit for possession of the pathological specimens and other property of the Institute.

Heredity.—Professor J. George Adami, of McGill University, Montreal, will deliver an address under the auspices of the Brooklyn Medical Club, on Friday, May 17th, at 8:30 P.M., in the Medical Library Building, 1313 Bedford Avenue, Brooklyn. His subject will be "The Medical Aspect of Heredity."

PHILADELPHIA.

Appointment of Dr. Kelly.—Dr. Aloysius O. J. Kelly, Instructor in Clinical Medicine in the University of Pennsylvania, was recently elected Professor of the Theory and Practice of Medicine in the University of Vermont. He leaves Philadelphia shortly for Burlington to begin his professional duties and will return to Philadelphia in the early fall.

Pay Hospital for Contagious Diseases.—The promoters of this enterprise state that the hospital will be in working order in the early autumn. One of the greatest difficulties to overcome has been the prejudices of citizens against the proximity of the building. An accessible site six miles from the City Hall, outside of the city limits, has been chosen. The entire cost of the hospital will be $100,000.

Homeopaths Demand a State Insane Asylum.—A deficiency bill carrying an appropriation of $1,000,000 now before the State Legislature bids fair to become available for charitable purposes. If this end is attained two institutions will probably benefit thereby. Members of the homeopathic medical fraternity are making a strong plea for an insane asylum to be under the control of the members of their school as there is not an asylum in Pennsylvania where a homeopathic doctor is admitted to practise. They ask for $200,000 with which to erect a building. The projectors of the State Hospital for Consumptives also desire an appropriation of $100,000.

Symposium on Diphtheria.—The meeting of the Philadelphia County Medical Society on April 24th was devoted to the above topic. Dr. J. D. Steele, in a paper on "The Present Aspect of the Antitoxin Treatment," gave statistics of the mortality-rate in Chicago, New York, Boston, and Philadelphia. These showed the latter city to have a higher rate than either of the others. Dr. Steele thought this due to a lack of energy in the prompt use of antitoxin. Dr. Packard believes it is caused by the failure of physicians to report many mild cases in order to prevent the quarantining of houses.

Clinical Aspects of Diphtheria.—Dr. F. A. Packard in speaking on the above subject said that bacteriological cases of diphtheria, *i.e.*, cases in which the bacilli are tolerated in the throat with no clinical symptoms are often a source of more danger to the community than are cases of clinical diphtheria. The absence of local discomfort is more suspicious of the Klebs-Löffler infection than of a pyogenic infection. Bleeding from the nose should excite suspicion of diphtheria. The pallor of the skin and mucous membranes of diphtheria is not seen in any other form of angina.

The Treatment of Diphtheria.—Dr. M. H. Fussell said that antitoxin given early is a specific. The only positive diagnosis of diphtheria is made from bacteriological examination of the throat but while waiting for this antitoxin should be given. He rarely uses more than 1,000 units at a dose, but repeats it unless improvement is rapid. Applications to the throat should be made or not made according to the individual. He has seen deaths result from persistent application to nervous, resisting children. Simple alkaline solutions are sufficient for applications, hydrogen peroxide not giving favorable results in his experience.

CHICAGO.

Bazaar at St. Luke's Hospital.—A bazaar was given at this institution a few days ago by the graduating class of the St. Luke's Hospital Training School for Nurses, netting $1,000, to be applied to the charity work of the hospital.

Nicholas Senn Hall.—A permit was issued April 17th for the erection of a seven-story addition to Rush Medical College, to be ready for occupancy November 15th. The building will be devoted to clinical instruction, and it is said it will cost $115,000.

Symptoms and Diagnosis of Gastric Ulcer.—At the meeting of the Chicago Medical Society, held April 4th, there was a symposium on ulcer of the stomach. Dr. N. S. Davis, Jr., read a paper with this title. Attention was called to the frequency with which the malady occurs. Many pathologists have found evidences of former gastric ulcer or existing ulcer in from three to ten per cent. of those who were examined at autopsy. The diminished acidity of the urine and the occurrence of an alkaline wave after meals, and the diminished amount of chlorides in the urine were described as evidences of hyperacidity of the stomach and as occurring in strange contrast to the conditions existing in cancer and chronic gastritis with which round ulcer is so often confused. Digestive leucocytosis exists in cases of gastric ulcer, but as a rule is slight or wanting, in cases of cancer and chronic inflammation. Persistent and even anemic leucocytosis occurs in most cases, of course, but does not occur in round ulcer. The ratio of hemoglobin to red corpuscles often resembles that of pernicious anemia in cancer, but that of chlorosis in round ulcer. In both maladies hemorrhages often reduce both equally at least for the time being.

Blind Medical Men.—A blind student was graduated with honors a few days ago at a medical college in Chicago. Aided by his highly developed senses of hearing and feeling, he hopes to become a successful specialist in the treatment of ills that have to be diagnosed partly by sound and touch. A sightless physician in Boston who died while yet a young man had already become noted as a specialist. There are several practising physicians in this country who cannot see.

GENERAL.

Bacterial Laboratory at Yale.—By a rearrangement of four rooms in Sheffield Hall a new bacterial laboratory has been constructed for the use of the senior class in sanitary engineering. It has accommodations for about twenty students.

Wheeling Medical Library Association.—About three years ago a number of the members of the medical profession in the city of Wheeling, West Virginia, realizing that the existence of a medical reference library for the Mountain State had become a necessity to the

intelligent study of the science of medicine, organized the Wheeling Medical Library Association. This association is now in a most thriving condition, having on its shelves over seven hundred volumes, and on file all the leading medical and scientific magazines printed in the English language. At their recent annual meeting the following officers were elected: President, Dr. Frank Le Moyne Hupp; Secretary and Treasurer, Dr. William Hay McLain; Librarian, Dr. J. Schwinn.

American Surgical Association.—The regular annual meeting of this Association for 1901 will be held in the city of Baltimore, at the Library Building of the Medical and Chirurgical Faculty of Maryland on Tuesday, Wednesday and Thursday, May 7-9, 1901. The program gives unusual promise. The President, Dr. Roswell Park, will deliver an address on "Some Phases of the Cancer Problem," and the following papers are announced: "Early Signs of Carcinoma of the Uterus" by T. S. Cullen; "Cancer of Breast Treated at the Johns Hopkins Hospital since 1889" by W. S. Halsted; "Late Results in Inoperable Sarcoma Treated with Mixed Toxins" by W. B. Coley; "Mental Depression and Malignant Disease" by J. D. Bryant; "The Examination of the Blood in Relation to Surgery" will be discussed by several. Drs. J. C. Bloodgood, J. C. Da Costa, Jr., J. B. Blake, J. C. Hubbard, R. C. Cabot, J. L. Kalteyer, J. B. Deaver and W. W. Keen will be among those who will contribute papers. Prof. Mayo Robson of England will read papers on "Pancreatitis" and "Treatment of Chronic Ulcer of the Stomach"; "Arteriovenous Aneurism" by R. Matas; "Operative Intervention for Tumors of the Liver" by W. G. Macdonald; "Subtrochanteric Osteotomy" by E. H. Bradford; "Phlebitis Following Abdominal Operations" by A. Vander Veer; "Operation for Radical Cure of Umbilical Hernia" by W. J. Mays; "Fractures and Dislocations of the Spine" by S. H. Weeks; "Radical Cure of Inguinal and Femoral Hernia" by W. B. Coley; "Resection of Chest Wall for Large Sarcoma" by W. W. Keen; "Pulmonary Insufflation" by R. Matas; "Silver Wire and Electricity in the Treatment of Aneurisms" by Leonard Freeman; "Movable Kidney" by M. L. Harris; "Abdominal Contusion and Nephrolithotomy" by S. J. Mixter; "Malignant Forms of Rodent Ulcer" by J. Collins Warren; "Congenital Sacrococcygeal Tumor" by Chas. A. Powers; "Vicious Circle after Gastro-Enterostomy" by T. A. McGraw; "Splenectomy for Myelogenous Leucemia" by M. H. Richardson; "Dislocation of Tibia and Arthrotomy" by J. B. Roberts and "Pneumonotomy" by W. Joseph Hearn.

Johns Hopkins University.—The Medical School has just opened several important special courses of instruction for graduates in medicine, which will continue during May and June. These new courses are intended to meet the requirements of practitioners of medicine, and are almost wholly of a practical character. Next October a limited number of physicians will be admitted to a special class for the study of the important tropical diseases, especial attention being given to malaria, dysentery, and typhoid fever. Preference will be given to officers of the medical departments of the army and navy.
